A REVIEW OF THE ADVANCES IN OUR KNOWLEDGE AND TREATMENT OF CANCER IN THE LAST THIRTY YEARS.*

By FRANCIS CARTER WOOD, M.D.,

NEW YORK.

DIRECTOR OF THE GEORGE CROCKER SPECIAL RESEARCH FUND, COLUMBIA UNIVERSITY.

But few discussions on the subject of carcinoma have been presented before this society. The subject is one which has not very greatly interested physicians, for the only treatment available has been operative removal. The recent extensive use of radium and *x*-ray, however, while unfortunately showing that these physical agents have much less therapeutic value than was originally believed, has turned the attention of physicians to the study of the nature and treatment of carcinoma, and I have, therefore, been asked by your President to give a review of the subject for the period since the foundation of the society in 1885.

It is obvious that only the main facts and but few of the workers in cancer research can even be mentioned in this address, and I shall be compelled to select those whose contributions seem to be the most important, and to disregard entirely the mere details of priority.

In the three decades which have just elapsed the real advances have been due to the introduction of the experimental method, so fruitful in other fields. No important additions have come from the clinical study of human cancer since Virchow laid the foundations and Waldeyer and Thiersch published their fundamental papers. It is true that our understanding of the morphology and classification of tumors has been amplified and the statistical study of large series of operated cases has led to an appreciation of the limits of surgery and the reasons therefor; but no new fact in tumor biology has been discovered by clinicians, though there are still many gaps which could be filled by careful observation. This review will of necessity, therefore, be confined largely to experimental results.

It has been my feeling that Jensen may be considered the Pasteur of cancer research, for it was he who by a series of painstaking observations first showed the possibility of the continuous transplantation of tumors from one animal to another through repeated generations, although, of course, others before him had published individual cases of successful inoculation. Jensen's first paper (1902) was published in Danish, so that his observations did not become generally known until some time afterward when the main points appeared in a German publication (1903). In this paper he described and illustrated the morphological appearances of tumors in mice; the transplantability of such tumors to other mice of the same race was demonstrated; and it was shown that tumors from albino mice could be transferred to the gray house mice in a small number of cases, but not to the more distantly related field mice, and not at all to animals of other species. He showed, also, that no parasites could be demonstrated, either by stains or by cultural methods, in the tissues of the transplanted tumors. He reported the effects of drying on the cells and their destruction by crushing or by ultraviolet light or by antiseptics, and showed that tumor cells could be kept alive at low temperatures [illegible] eighteen days, although they died off rapidly [illegible] C. He was the first to call attention to [illegible] the growth of the tumor depended [illegible] ization and the necessary con[illegible] tions which accompany the phe[illegible]ing upon this point as important si[illegible]ved that the disease is not an infection, b[illegible] the tissues of the host replace the connective tissue of the original tumor and thus nourish the epithelial cells, which alone are propagated in the body of the new host. All of these points have been repeatedly investigated without in the least invalidating any of Jensen's conclusions. In the same paper, however, Jensen fell into an error by claiming that by the injection of tumor tissue into rabbits he had obtained a serum which had beneficial effects on tumors of mice. Later, he acknowledged that the error was due solely to his lack of knowledge in regard to spontaneous regression of transplanted tumors in animals. Almost every year since that time this error has been repeated, both by laboratory workers using animals and by clinicians in the treatment of human beings, the most recent instance being the now generally acknowledged failure of Hodenpyl's attempts to cure carcinoma by the injection of serum from a patient with ascites following invasion of the peritoneum by a malignant growth. Even laboratory men do not seem to have learned the lesson that the biological behavior of a transplanted tumor must be accurately determined before therapeutic measures can be tested on it. The numerous reports on the power of diet, drugs, radium, and other agents to induce the disappearance of a tumor are vitiated by disregard of this elementary fact. A number of recent reports have been based upon observations on the Buffalo rat sarcoma, so-called, which has the power of spontaneous regression in various series of from five to forty per cent. Obviously such a tumor should not be used for testing therapeutic agents; only one which grows progressively in from ninety to one hundred per cent. of animals will afford reliable data.

*Read at the thirtieth annual meeting of the Association of American Physicians, in Washington, D. C., on May 11, 1915.

About the same time as Jensen, Leo Loeb and Borrel also demonstrated many interesting facts concerning the transplantability of new growths, but the next really important advance was made at the State Institute for the Study of Malignant Disease at Buffalo, under the leadership of Gaylord (1906). It was from this laboratory that the first definite proof was offered that spontaneous regression in transplanted tumors in animals is not infrequent, and that following such regression the animal may be immune to succeeding inoculations. Gaylord also introduced a very useful system of making charts for record, which was improved and extended in Bashford's laboratory, and should be more generally used by those working on this subject, as it offers an admirable means for judging at a glance of the rate of growth and regression of a long series of tumors.

Carcinosarcoma.—The genius of Ehrlich and his able assistant Apolant added (1905) the important experimental observation that certain carcinomata of mice may, during growth, produce a sarcomatous alteration in the stroma. Since that time a considerable number of these tumors, still less than a dozen, however, have been studied and the histological changes have been fairly well determined. It was shown by Haaland in Bashford's laboratory that the sarcomatous and carcinomatous portions could be picked out of sections of the tumor and each propagated separately, retaining the morphological characteristics of the original. Russell in Bashford's laboratory, also, showed that the condition developed usually after a certain period of growth in the carcinoma (some forty to fifty days in the tumors which he studied), and that there was a tendency for the sarcoma ultimately to replace the carcinoma. The importance of these observations lies in the fact that this is one of the few instances in which we are able to watch the origin of a new growth. While it is generally observed that in man the production of a tumor follows chronic irritation only over a very prolonged period, for example, *x*-ray carcinomata usually appear from eight to ten years after the primary injury of the skin, yet here in these small experimental animals the tumor is produced in fifty days. An explanation is not forthcoming. It may be, however, that in the mouse the period of fifty days corresponds to ten years in a human being. Unfortunately, these growths are very rare, and because of the scarcity of material the various interesting and important experiments which have suggested themselves in the last few years have not been possible.

Tumor Immunity.—Ehrlich (1906) as a result of his studies on the question of immunity to tumor implantation, brought forward his well-known theory of athrepsia, which may be stated briefly as follows: A tumor in order to grow continuously in an animal requires certain specific substances which permit of this growth, the nature of these substances being entirely unknown; if they are not present the tumor does not grow; when they are exhausted the tumor undergoes spontaneous regression. Like so many of Ehrlich's theories, whether right or wrong, this has led to a very large amount of important work on the nature of the resistance to tumor growth. At present, however, it is generally held that the athrepsia theory is not the best explanation of the phenomenon of resistance but that the process depends upon the vascularization of the graft by the blood-vessels of the host. If this does not occur the tumor does not develop.

This phase of the problem has been most thoroughly examined by Russell in Bashford's laboratory, and additional work has been done by Woglom and Burgess. To these workers the immunity seems to be directed against the chemotactic influences exerted by the cancer cell upon the connective tissues of the host. There must be present in the resistant animal, either in the circulating fluid or in the tissues, something which inhibits this chemotaxis, although all attempts to determine the presence of this active cell poison have been inconclusive. It is certain that this anti-substance is not very active, for the cancer cells continue to retain their proliferative power for seven to ten days in an immune animal. At the end of this time the cells begin to die, and the graft becomes surrounded by an inflammatory exudate which impairs the nutrition. The peripheral extension of the tumor cells ceases, central necrosis occurs, and ultimately the entire mass undergoes necrosis and absorption. Da Fano (1912) has called attention to the fact that in regressing carcinomata a large number of plasma cells and lymphocytes were found in the tissues about the growth, and he thought that the immunity was in some way correlated with the presence of these cells, a point which Murphy later used very effectively.

Heredity.—In 1911 Murray of the Imperial Cancer Research Fund published the results of careful studies on highly inbred strains of mice, two groups of which had been selected: one in which a recent ancestor was cancerous, that is, the mother or one or both grandmothers or all three was cancerous, and the other in which no cancer had occurred in either the mother or grandmothers. Comparing the offspring of these two groups, it was found that in those of cancerous ancestry eighteen per cent. developed tumors in later life, whereas in those with non-cancerous ancestry only eight and six-tenths per cent. bore tumors. Actuarial discussion of the statistics led Murray to the view that the disparity between the two groups was not due to chance, but, on the contrary, was significant, and that the increased liability to cancer was in all probability in the nature of a predisposition of one organ or tissue to undergo cancerous transformation under conditions as yet not understood. These observations have been extended by Tyzzer, Leo Loeb, and Maud Slye. The results obtained by Miss Slye and by Loeb confirm Murray's conclusions, but the subject still needs a great deal of study. Apparently not all groups of mice can be bred so as to show cancer heredity; this is possible only with certain strains. Miss Slye thinks that even organ liability can be transmitted; that is, that by suitable breeding a susceptibility to a tumor of a given organ may be carried down to succeeding generations, but this statement needs much further confirmation, both from the author and from some independent source.

The statistical study of human cancer has as yet given us no reason to think that heredity plays any part in the occurrence of the growth.

Conditions of Metastasis.—The variation observed in the metastatic spread of neoplasms has always excited a great deal of interest, two somewhat conflicting views being held: one, that the extent and relative liability to metastasis are dependent on purely mechanical factors only, the size of the cells and the vascular relationships; the other, that the soil in the various organs differs in its suitability.

Tyzzer has shown recently that massage of a tumor greatly increases the number of metastases, an observation strengthening the first theory; while careful comparison of the susceptibility of different organs by inoculation tends to show that there is little or no variation, provided the tumor cells are deposited in proper amount.

Explants or Tissue Cultures.—That tissue cells may grow independently of the body has been known since 1906. This property of cells was made use of by Lambert and Hanes (1913) to show, first, that tumor cells will grow in the plasma of alien species, though no growth is obtainable in the tissues of such a host; and, secondly, that tumor cells grow just as vigorously in the blood of animals immune to the tumor as in that of those free from such inhibiting powers. This demonstrates that tumor immunity is not due to antibodies present in the circulating blood.

Chicken Sarcoma.—Peyton Rous of the Rockefeller Institute in 1910 discovered in a Plymouth Rock hen a large tumor of the right pectoral muscle. Inoculations of this growth into other hens resulted in the obtaining of a single large secondary mass. Further transplantations were more easy, and the tumor is now an extremely malignant sarcoma which forms metastases all over the body with the greatest rapidity and kills the inoculated animals in from fourteen to eighteen days, growing in practically all of the animals inoculated. It is a sarcoma with small spindle or fusiform cells, and is usually extremely well vascularized. It does not now form nodular masses, but gives rise to a diffuse infiltrative growth throughout the organs which it involves. Metastasis takes place through the blood-vessels. The point of especial interest about this tumor is that when the growth is ground up and passed through a Berkefeld filter No. 5, which is impermeable to the *B. prodigiosus*, the resulting fluid is capable of giving rise to a new tumor when inoculated into a susceptible fowl. The same is true when tumor tissue, after being ground and dried, is inoculated, and even also when the tissue is suspended in 50 per cent. glycerine. After heating to 50° C. for fifteen minutes, the tumor will not grow in vitro, but such heated material when inoculated into susceptible fowls gives rise to growths. The obvious interpretation of the phenomena just mentioned is that the tumor is transmitted by an invisible and filterable virus. No parasite can be demonstrated, however, in ultramicroscopic preparations, even though the filtrate is capable of giving rise to tumors when injected. On the other hand, it is not possible to immunize against this tumor by the injection of embryo skin or whole embryos. This is, however, not an absolute proof that it is not a tumor of the ordinary type, because immunity can not be produced against all varieties of tumors. Another curious fact is that no complement fixation is found in the blood of chickens carrying this tumor when the tumor itself is used as an antigen. This points somewhat to the fact that there is no parasite present. We evidently have here a tumor of an entirely different type from anything known in human oncology.

Heterologous Transplants.—Murphy (1914) having noticed that the growth of tumors of the mouse and rat in chicken embryos was halted at the period when development of the spleen and bone marrow began, conceived the idea of attempting heterologous transplants in adult animals in which the lymphocytic reaction of the tissues had been inhibited by preliminary treatment with the *x*-ray, basing his premises also upon the work of Bashford and Da Fano and Roux, who have shown that in regressing tumors a great collection of lymphocytes and plasma cells occurs about the graft. In rats treated with the *x*-rays, he was able to grow mouse carcinoma for thirty-two days, apparently confirming many of the previous suggestions that immunity to tumors lies in the tissue rather than in the serum.

Nematodes as a Cause of Cancer.—Borrel has long believed that certain parasites are related to the occurrence of cancer; and Haaland has also stated that nematode worms are frequently present in breast tumors of mice. The scientific world was greatly interested, therefore, when Fibiger reported (1914) that he was able to produce tumors of the rat stomach by feeding certain nematodes which are parasitic in the cockroach. These tumors, as a rule, do not extend beyond the walls of the stomach and involve only the portions covered with squamous epithelium, but in several cases it was thought that there were metastases in the lungs or lymph-nodes; apparently, however, no attempt was made to transplant the tumors and the observation must remain as unconfirmed. Experiments in my own laboratory with the feeding of cockroaches which were known to contain the nematode in question have not resulted in any very marked hyperplasia of the gastric mucosa, and, in fact, far greater hyperplastic growth, with invasion of the submucosa and muscularis quite corresponding to the tumors which Fibiger reports, has been produced by the continuous irritation of the mucosa of the stomach with certain chemicals. These results cast some doubt on the specific nature of the parasitic irritant, which Fibiger assumed. Some of those who have seen Fibiger's sections doubt, also, the metastatic nature of the lung growths, believing rather that they represent heterotopic epithelium from the nearby bronchi. If, however, Fibiger's tumors prove to be actual malignant growths, this will be one of the very important examples of our ability to produce at will, by chronic irritation, a tumor corresponding to the well-known *x*-ray carcinomata, of which many examples have been seen in man and a few in animals, notably in some experiments of Clunet, after continuous irritation with the *x*-ray.

Theories of Neoplasia.—Much of the immunological investigation in cancer has been based upon the assumption that there is some close correlation with the facts of bacterial immunity. On the contrary, however, the conditions which permit bacteria to flourish are actually just the opposite to those under which tumor cells can grow in the tissues. Bacteria are active invaders of the host tissues, either fluid or solid, and act as antigens, often growing in spite of the development of a large number of antibodies which may or may not ultimately destroy the parasites. The tumor cells, on the other hand, are not parasitic in their incipiency, but rather commensals, acting parasitically on the host only when the growth exceeds a certain volume. If the tumor cell excited an immune reaction at its inception it would be destroyed, as any aberrant body cell is by lack of nutritional supply owing to the fact that vascularization does not occur. Epithelium placed in the peritoneal cavity of an animal excites a reaction which results in a prompt destruction. A group of tumor cells, on the other hand, excites no reaction, but is soon vascularized, and, hence, survives. Both types of cells grow with ease in the plasma of the

animal whose tissues have rejected one form and cared for the other; hence, the conditions of growth are not dependent upon the body fluids, but upon the tissue cells themselves, the condition being not a positive reaction against them, but rather the occurrence of vascularization which permits the cancer cells to establish themselves. The normal cells, on the other hand, incite a reaction which leads to their destruction, and it is, therefore, impossible to produce a tumor by the injection of normal epithelium, glandular structures, or connective tissue cells.

Treatment.—A few words will suffice to sum up all that we know as regards treatment of carcinoma. No simple chemical or complex organic body seems to have any permanent influence on tumor growth. Colloidal metals, autolysates, and bacterial toxins, have not the slightest curative power in carcinoma either of man or of animals. A combination of selenium and eosin, so widely vaunted by v. Wassermann, has failed to fulfill its promise. Physical agents, such as *x*-rays and radium, have some actual power, but only in the superficial or less malignant forms of tumors. That early operative excision is still the best therapeutic procedure is shown both by animal experiments and by clinical experience.

Thus, despite the most painstaking experimental study, the garnering of thirty years' work shows a surprisingly small harvest, not at all comparable with the amount learned during the same time concerning bacterial and tissue immunity. The problem seems much more difficult owing to the many variables always to be considered in working with so highly specialized and susceptible a cell as that of mammalian cancer, and because reactions following the implantation of tumor cells into the tissues are wholly different from those following the introduction of bacteria or simpler cells, such as red blood corpuscles. In fact, the striking phenomenon is that they do not produce any of the ordinary immune reactions, perhaps because they grow only in a host of the same species, for when introduced into another species, immune bodies of a non-specific nature only, exactly comparable to those induced by normal cells, are produced.

THE TRANSITION OF GASTRIC ULCER INTO CARCINOMA AND OF GASTRIC CARCINOMA INTO ULCER.

A DISCUSSION FROM THE CLINICAL AND PATHOLOGICAL ASPECTS OF THE SUBJECT.

By J. C. HEMMETER, M.D., PH.D., LL.D.,

BALTIMORE, MD.

PROFESSOR IN THE UNIVERSITY OF MARYLAND.

Clinicians of conservative critical judgment and broad experience have taken the statement by American and English surgeons that carcinoma of the stomach originates on the basis of a pre-existing gastric ulcer in from 66 to 71 per cent. of the cases with unavoidable scepticism because their experience must have taught them that usually cases of gastric ulcer under proper treatment heal perfectly, and when they can be observed 10 to 20 years afterwards no history of secondary consequences can be elicited.

In a recent communication A. Billeter,[1] who gives a report of 116 observations of the surgical clinic at Zürich, refuses to interpret a cancer that developed 10 years after the history of the healing of an ulcer as a secondary cancer. This conception should appeal as rational to every objective thinker, for 10 years is too long a time to permit the correctness of the argument that a possible development of cancer might still be due to the ulcer that had healed a decade previously or due to a scar. It is just as likely that the cancer was a primary one developed independently of the scar. The proof of an etiological connection between the two conditions can clinically be given in only a small number of cases.

This subject can be studied by four methods: (1) Statistical method (in the manner advocated by Quetelet[2] and De Candolle[3]). (2) The method of long clinical observation after operation of gastroenterostomy, the ulcer remaining *in situ*. (3) The method of many years of observation and of study of cases, after treatment by rest, diet, internal medication, and duodenal feeding. (4) Method of pathological histology.

The Question of Carcinomatous Degeneration of a Chronic Gastric Ulcer.—According to Prof. Dr. G. Hauser of Erlangen,[4] the opinion that a chronic gastric ulcer may degenerate into a carcinoma has been admitted by different pathologists and clinicians as based on the wide anatomical similarity of many carcinomatous ulcers to old typical gastric ulcers. It was partly based on a clinical observation that the carcinoma may be preceded by a more or less prolonged period of symptoms which are characteristic of a simple gastric ulcer, but the majority of cylindrical cell or adenocarcinomas of the stomach give no such anamenesis.

According to Hauser it cannot be denied that, notwithstanding the great anatomical similarity which exists, this is not sufficient ground upon which to base a probability of a secondary development of carcinoma on a primary gastric ulcer. An exception to this statement is found in the partial carcinomatous degeneration of a cicatrix. There are a number of cases in literature in which no sufficient reason existed in the clinical history to vouchsafe the secondary development of a carcinoma on the basis of a gastric ulcer. This question is of the greatest importance not only for the chronic gastric ulcer, but also for the entire theory of cancer.

It was desirable to investigate whether characteristic evidences could be found by histologic examination which were sufficient to establish with certainty the pathogenesis in such cases.

The following is mainly an abstract of the convictions of C. Hauser, with whom the author has personally conferred and who has made this special subject of pathology his life's work. This question was studied in a former paper, with the result that there exist distinctive histological signs that indicate the secondary carcinomatous degeneration of a previous ulcer, *provided that the cancer has not proceeded too far.*

The following signs seem to prove the secondary character of a carcinomatous degeneration: (1) The muscular coat at the edge of the ulcer is curled or rolled up. The outer border is separated by a well-defined line of demarcation from the remaining floor of the ulcer. (2) The carcinomatous infiltration of the floor of the ulcer is only partial.

This appearance of the muscular coat is characteristic of large and deep simple chronic ulcers which permeate the entire stomach wall. This ulcer can only form if the submucosa is still elastic and unchanged, and provided that the muscular layer has not been bound down by carcinomatous

infiltration, which transforms the entire stomach wall into a rigid inelastic mass. This view was generally endorsed later on.

Ernst Adolph Schmidt,[6] in discussing the report of Hirschfeld on the "Relation Between Gastric Cancer and Ulcer," ventured to suggest as follows: "I cannot deny that it is difficult to decide whether gastric ulcer means the primary, and cancer the secondary, process in cases where, at post-mortem examination, we find more or less extensive ulcers the size of a 25-cent piece, which are surrounded by an area of carcinomatous infiltration and which occupy the periphery of the carcinomatous growth. We know definitely that such a loss of substance can occur in a very short time, in one or two days (Schmidt admits even a shorter period). The possibility of such an extensive carcinomatous infiltration of the stomach wall arising in so short a time may be granted, but has not been positively ascertained. Schmidt thinks the carcinomatous tissues more vulnerable, that they decay more readily, and once an ulcer has been formed the healing process is far more retarded than in an area where the infiltration takes place at a later period. Schmidt and Hauser do not exclude the possibility that a proportion of ulcers, interpreted as carcinomatous, must be explained in just a contrary way as was customary until now. If such is the case the relation becomes more defined and speaks more in favor of a causal coincidence. Hauser remarks that for the development of an ulcer the period required for its formation may be shorter than two days. An artery of the stomach being occluded or cut off by any cause from the general circulation the immediate result is necrosis and hemorrhagic infarction of the area in question. Therefore, the ulcer can develop as rapidly as the digestion of the necrotic area advances, which process can hardly require more time than the digestion of an ordinary small piece of meat."

The carcinomatous infiltration requires a much longer time than one or two days. No one has ever reported such a rapid course in cancers visible to the eye, no matter how malignant. Only in ulcers running an extremely chronic course has a secondary carcinomatous degeneration been observed. This applies particularly to cases in which for mechanical reasons the healing process is rendered exceedingly slow and difficult or impossible. These ulcers are located usually at the pylorus (small, deep, crater-like with steep ascending edge, undermined borders, or large ulcers strapped down by adhesions with other organs—pancreas most often found adhering to stomach).

Both types of ulcers show marked chronic inflammatory proliferation of the adjoining submucosa and of the interstitial tissue of the muscular coat, the latter being generally hypertrophied considerably in the region of the pylorus. The clinical course in such instances is very chronic. Secondary carcinomatous degeneration of scar tissue, though admitted as a possibility, is very infrequent.

The question raised by E. A. Schmidt, whether a supposedly secondary carcinomatous degeneration of a simple chronic gastric ulcer cannot also be interpreted as originating in the reverse manner, viz., that an ulcer may result as a consequence of the autolysis of preceding gastric cancer. I have myself observed one such case for eleven months, where the chemical and microscopic findings and gastroscopic examination spoke for cancer, but the eroded area is becoming smaller and smaller (under duodenal feeding) and now looks like an ulcer under the gastroscope. Operation was refused, the patient is gaining weight.

The question of malignant degeneration of a gastric ulcer is, clinically speaking, of the greatest importance. The hyperacidity, although formerly thought of great importance for the etiology and symptomatology of gastric ulcer, is not now considered of so great importance, according to Kayser.[7] Yet complete loss of free HCl in cases of chronic gastric ulcer must occur extremely rarely.

Clinically, such cases of chronic gastric ulcers which have developed from a pre-existing carcinoma are exceedingly rare. *The combination, however, of separate and distinct cancer together with ulcer in the same stomach is possible,* and Hauser reports such a case of a woman 63 years old with no free HCl, distinct lactic acid in a fasting stomach and after a test breakfast. In that case a combination of a scirrhus carcinoma of the stomach with *two* recent peptic ulcers was found, one a carcinomatous ulcer (macroscopically and microscopically).

The continuation of a cicatrix in one place and an adenocarcinoma 5 inches from it in the same stomach was observed by me in 1898 (University Hospital), and in a second autopsy the occurrence of a cicatrix 1½ inches from the pylorus and a cylindrical cell carcinoma in the middle of the lesser curvature. These cases demonstrate that gastric cancer can occur simultaneously with scars and that the latter are not necessarily places of predilection.

Adenocarcinomata have been pictured limited to the submucosa where no break of the cylindrical epithelium nor of the glandular layer overlying them was detectable. Such carcinoma also cannot be conceived as arising from ulcers or scars, where no trace of these can be found. (See also similar conditions of sarcoma in the *Archiv für Verdauungskrankheiten*, May 1914, p. 179.)

The history of Hauser's patient was negative until a few weeks preceding death (anorexia and dyspeptic symptoms). It cannot be denied that the scirrhus cancer followed a slow development, probably lasted several months before any clinical manifestations were obvious. Both simple ulcers, one a perforating ulcer in this case, must have been formed only a short time before death and arising from hemorrhagic infarction and thrombosis of the gastric vessels. It must be striking that, notwithstanding the lack of free HCl, these two ulcers could develop so rapidly; perhaps this was due to a specific peptic ferment found in carcinomatous growths (O. Neubauer and Fischer[8]).

The questions which arise from such an observation are difficult to answer as to (1) whether the ulcer found in the area of the scirrhus and those two simple peptic ulcers were formed simultaneously, or (2) whether the first ulcer, carcinomatous in nature, had existed previous to the formation of the peptic ulcer.

The lack of any inflammatory infiltration at the border and at the bottom of the ulcer which Hauser describes is not convincing proof that the ulcer had been formed just recently. Based upon my own experience with carcinomatous ulcers of the rectum, which, according to clinical observation, existed for a long time, an inflammatory infiltration can be entirely absent, not only in the floor of the ulcer

but also on the surface. Only in the recesses of the ulcer, where no stagnation of the intestinal contents could take place, a more pronounced inflammatory irritation and infiltration could be observed. Hauser concludes that the carcinomatous ulcer existed for some time previous as a "torpid" (?) ulcer, but that in different spots in the border of the ulcer *small necrotic areas must have developed, probably simultaneously* with the other simple ulcers, and very likely all these were due to the same cause. Such a statement is corroborated by the small microscopic brown sloughs in the recesses of the ulcer; furthermore, the recent necrosis in the upper layers of the bottom of the ulcer and in the border of the adjoining mucous coat, as well as by the capillary congestion. *In this case we have not only fresh typical peptic ulcers existing with an already formed carcinomatous ulcer, but also within the area of the latter fresh necrotic defects have been formed.* On the pathological findings of this case Hauser endorses the conception of Schmidt that seemingly secondary cancer development in association with a chronic gastric ulcer is explainable in a reverse method, and he believes this explanation is justified, namely, the ulcer is the result of the cancer.

The question arises, How can a differential diagnosis be made? Cases as these described offer no diagnostic difficulties with regard to existing relations between both processes. Notwithstanding the topographical relations between the simple ulcer and the cancer, if, as in Hauser's case, the peptic ulcers show all characteristics of recent formation, then it is evident that the cancer must have existed a long time before the simple ulcer has been formed. Doubt may only arise in cases in which, after the formation of a fresh ulcer on a carcinomatous basis, the patient remains alive long enough to give time for the development of changes in the ulcer which no longer permit us to ascertain its age in relation to the carcinoma.

According to the location of this type of gastric ulcer, two possibilities have to be considered, namely: (1) The peptic ulcer has been formed in the center of an already existing carcinomatous infiltration, or (2) the peptic ulcer has been formed at the border of a pre-existing carcinomatous area.

In the first instance—namely, where the hemorrhagic sloughs have been cast off—*even though extensive cancerous infiltration of the bases of the ulcer is evident, Hauser considers a decision as to which was the primary cancer or ulcer impossible.* This is true even if the ulcer present in every particular resembles a simple gastric ulcer. So Hauser attributes the greatest importance to persistence of hemorrhagic infarct sloughs, long enough to be recognized by the pathologist. These sloughs arise from the hemorrhagic infarcts that are formed when the gastric ulcer has its origin. Once they have disappeared *no decision as to the combination and relation of ulcer and cancer is possible.*

Within the area of the stomach wall which is involved by deep carcinomatous infiltration the formation of a typical peptic ulcer never occurs, as the arrangement and distribution of the vessels supplying the stomach wall in the location also undergo changes which will bear upon the outspread of the carcinomatous infiltration and of the carcinomatous stroma. The typical form of the peptic ulcer at the beginning is dependent upon the form of the normal blood vessels and vascular distribution. Thus an ulcer of typical shape—that is, a circular ulcer with well defined borders, crater-like or funnel-shaped, situated in the center of a carcinoma, even with complete carcinomatous infiltration on the bottom of the ulcer—rather favors the theory of a secondary carcinomatous degeneration of a preceding simple ulcer than of a carcinoma complicated by an ulcer.

It must be admitted that an ulcer may secondarily arise from a deep-seated loss of substance within a flat carcinomatous area which reaches as far as the submucosa, or as far through as the internal layer of the muscularis. The floor of the ulcer may appear, for some time at least, exempt from carcinomatous infiltration, analogous to the condition where a chronic gastric ulcer degenerates by a secondary malignant process.

If we encounter only small ulcers within an extensive carcinomatous infiltration, we are forced to admit that the ulcer has been formed at a later period, for in cases with secondary carcinomatous degeneration of small ulcers the carcinomatous infiltration must have completely involved the entire bottom of the ulcer a long time before the carcinoma has spread toward the periphery. Hauser states that he has not met such cases personally.

If we have to deal with an ulcer answering the typical form of a peptic ulcer, where the bottom shows no carcinomatous tissue and in which is found only a small degree of carcinomatous infiltration that can be detected near the margin, particularly in more extensive ulcers, we can admit that an originally simple ulcer has degenerated secondarily into cancer, for the interpretation seems unnatural and forced that a typical peptic ulcer should have formed just in the center of a carcinomatous area, so that only a small marginal zone of carcinomatous infiltration would remain. This would also indicate that previously a simple ulcer existed and that the carcinomatous degeneration along its borders took place at a later period. In both instances one may incline to the opinion that a simple chronic gastric ulcer existed at first, per se, and was eventually invaded from one side by a carcinoma immediately adjoining it. In the case of deep ulcers, as have been described repeatedly, a very characteristic sign is presented, namely, the appearance of the muscularis at the bottom of the ulcer.

Considering the second possibility, that a peptic ulcer may develop independently of a neighboring carcinoma and right from the start, it might be located within the area of carcinomatous infiltration, or it may happen to be developed so close to the carcinoma that this, during its further outspread, may extend to the border of the ulcer. Three histological possibilities are now acknowledged: (1) A gastric ulcer has developed from a pre-existing carcinoma. (2) A carcinoma has developed secondarily from a pre-existing gastric ulcer. (3) Both carcinoma and gastric ulcer, or scar, may occur in the same stomach simultaneously, with no traceable pathogenic relations between the two conditions. When an ulcer is either located from the start within an area of carcinomatous infiltration or so near to a cancer that this readily can extend to the border of the ulcer, then in both cases we are dealing with a simple chronic gastric ulcer, the edges and base of which have become infiltrated with extending cancer, and there can be no doubt that the *ulcer arose secondarily from an already existing carcinoma.* If, under such anatomic conditions, we are dealing with an

extensive carcinoma, there can be no doubt that *the ulcer developed secondarily from a cancer that already existed.* For, considering the peculiarity of growth of carcinomas, it is impossible that a cancerous infiltration arising from the edge of a simple chronic gastric ulcer could etxend only to one side and leave the base free.

To Hauser's knowledge, no such cases have been discussed in literature. His case described before, however, speaks in favor of such a possibility, for if the patient had lived for a longer time after the formation of the ulcer, the further outspread of the cancer would have reached the floor of the ulcer. He admitted the possibility that the tough connective tissue of the base of an old ulcer may offer a greater resistance to the progression of cancerous infiltration than the adjoining tissue at the margin of the chronic ulcer. Cases, however, where only a *small* carcinomatous proliferation is found in the border of an old and more extensive ulcer may be interpreted as ulcers with *secondary carcinomatous degeneration.* This is even more true of such cases in which different sections of the border show a carcinomatous change of the mucosa where the degenerated glands have penetrated into the submucosa, notwithstanding the fact that the bottom of the ulcer may show no carcinomatous change whatever.

Doubtless a secondary formation of cancer must be admitted where a carcinomatous infiltrated area is found in the case of an old linear scar, as in an hour-glass stomach. It is altogether excluded that a peptic ulcer has been formed within a primary cancer, which ulcer could extend further than the cancer. Also, the possibility may be excluded that within a carcinomatous infiltrated area a scar could be formed which extended further than the malignant area. Such a formation of scar tissue never takes place within the area of a cancer of the mucous membrane. Hauser describes having seen quite a number of scars in which cancer has developed.

Therefore, in the majority of cases the anatomical condition and the microscopical examination, whenever the cancer infiltration has not proceeded too far, enable us to obtain reliable evidence for the judgment and interpretation of such conditions, i.e. whether secondary carcinomatous degeneration of a chronic gastric ulcer, or whether a secondary condition of peptic ulcer with a pre-existing carcinoma exists. This is true, provided that the carcinomatous infiltration has not gone too far, which is the case, as a rule, where the tumor mass already exists.

We have to consider that a *combination of carcinoma with ulcer is exceedingly rare*, otherwise one should find peptic ulcer more frequently associated with carcinoma. The simultaneous finding of scars cannot be considered, as these may have existed a long time before the development of a cancer. Clinical observation also points with great certainty to the possible development of a carcinoma arising from a pre-existing ulcer, although a definite diagnosis of a gastric ulcer may be quite difficult. For instance, a case observed by von Leube and described in Hauser's monograph on "Cylinder-Epithelial Carcinoma" must be interpreted in a similar way (case 37). In this case symptoms of a chronic gastric ulcer (three years previous to operation hematemesis and occult blood in the feces) existed. In the course of the operation (resection) a deep ulcer, as if punched out with a tool, was found answering the typical form of chronic ulcer, with only a small extent of carcinomatous infiltration. Also, two lymph glands with carcinomatous infiltration were encountered. Any other interpretation than that of a secondary cancerous degeneration of an ulcer is impossible in this case, for a gastric cancer, especially of the type of a simple cancer in its transition to a medullary cancer, as ascertained by histological examination, in this instance becomes fatal within two years. The case of *ulcus carcinomatosum* of the stomach described by Hemmeter and Delano Ames[10] had been under clinical observation from June, 1895, to February, 1897, when life was ended by a supervening phlegmonous gastritis with perforation.

The six macroscopic and microscopic drawings (by H. Becker) published in this article demonstrate adenocarcinoma developed on the basis of a pre-existing gastric ulcer.

Based on statistical tables concerning the frequency of ulcers and cancers in different cities, Hirshfeld concludes that no connection exists between chronic gastric ulcer and gastric cancer. Hirshfeld[11] writes: "It is evident from these tables that in three cities, Zurich, Munich, and Vienna, gastric ulcer occurs with equal frequency and about 3 per cent. of all patients entering hospitals for treatment are affected with it. In Berlin and Hamburg, in which places similar conditions prevail, this rises to 7 per cent. There are about twice as many persons in Hamburg and Berlin suffering from gastric ulcer as in Zurich, Munich, and Vienna. We could expect that gastric cancer would be found twice as often in the postmortem reports of Hamburg and Berlin as they are found in the autopsy records of Zurich, Munich, and Vienna. This, however, is not the case, for from numerous publications it is evident that gastric cancer occurs with a somewhat smaller frequency in Hamburg and Berlin than it does in Zurich, Munich, and Vienna."

Oberndorfer[12] published statistics based on a careful investigation, according to which gastric ulcer has been found not only in 3 per cent. but in 7 per cent. of all cases examined, and particularly found in the 5th to the 7th decade. Based upon these statements, Hauser is inclined to consider the statistic tabulation of Hirshfeld as weakened. But a comparison of the ages at which death occurred in Hirshfeld's and Oberndorfer's tables will explain the discrepancy.

Oberndorfer[12] published statistics coming also from the city of Munich (Krankenhaus Links der Isar), in which he endeavors to show that gastric ulcer occurs with a much greater frequency in Munich than Hirshfeld indicates. Oberndorfer gives the enormous number of seven per cent. (7 per cent.), which I am disposed to doubt, for in Oberndorfer's statistics there is no punctilious regard for age of the deceased, and if we take principally the fifth to the seventh decennium, in which Oberndorfer's cases happen to fall, there must necessarily be a larger percentage of gastric ulcer than if the deaths from the age of 30 years up to 80 are taken as Hirshfeld's "Age and Case Statistics" demonstrate.

Kayser[7], in his interesting examinations collected in the clinic from von Müller on gastric ulcer, reaches a conclusion similar to Oberndorfer's. He concludes that ulcer may pursue a latent course, that it is more frequently present than it can be recognized clinically. I fail to appreciate how a "latent" course of gastric ulcer should figure in this

scientific discussion, for cancer can also occur in a latent manner and there can be no criterion how frequently either condition may be *latent*, for the very word "latent" means that the condition is not recognized.

Kayser also insists that all previous statistical data of the pathological anatomy of gastric ulcer are subject to criticism, as sometimes ulcers and their scars together, at other times the cicatrices alone, have been considered in these statistics. He points out that a single stellate scar can be entirely overlooked at autopsy, and statistics which either consider or do not consider such a possibility must differ considerably and, therefore, must present a different value. It depends whether such statistics have been based on old postmortem reports from autopsies done by others and collected by inexperienced examiners, or whether the man who compiles the statistics has himself for years paid special attention to gastric ulcers proper and to scars arising from such conditions, and whether they have been properly emphasized in the protocol.

The question of further and great importance is what clinical significance has to be attached to the secondary carcinomatous degeneration of a chronic gastric ulcer and whether such a condition is frequent or only very seldom and exceptional, compared with the proportion or frequency of gastric ulcer. The positive interpretation as in the reported case, whether a secondary carcinoma developed as a consequence of a preceding chronic ulcer, is not easy, as it requires a minute and careful examination, and such a degree of expertness and knowledge in pathologic histology that has not been evident in all cases published in literature. Unless such broad experience in the reporter is evident his work offers an opportunity for criticism. The answer to that question according to Hauser's present knowledge (1911) cannot yet be given.

Considering the following points, the decision whether a cancer can secondarily develop (*a*) within the border of a chronic ulcer, or (*b*) from the floor of an old scar tissue of an ulcer, these conclusions are only possible in recent stages of carcinomatous development. Further, Hauser thinks that as the chronic gastric ulcer is more frequently present than can be diagnosed clinically, we can logically conclude that the carcinomatous degeneration of a chronic gastric ulcer or of a scar must in reality be more frequent than it is ever possible to ascertain by pathological, anatomical or clinical observation. The fact that peptic ulcer and gastric cancer show the same places of predilection with regard to their seat would suggest that such a topographical relation between ulcer and cancer of the stomach is by no means a rare one. This sentence was written by Hauser in 1910, but in a letter he wrote to me (Hemmeter) in 1913 he states that *it is impossible to decide from a small piece obtained at operation whether a gastric carcinoma has arison from a pre-existing peptic ulcer or not.* And as a great many opinions as to the pathogenesis of gastric cancer are based on examination of such small pieces gained at operation, they fail to carry conviction.

The statistics from the surgical clinic of Zurich published by Billeter[5] show conclusively that ulcer of the stomach rarely metamorphoses into cancer.

Opposed to the communications of American and English surgery, according to which a large percentage of gastric cancers are believed to have originated on the basis of a preceding gastric ulcer, we find the following conclusions of German authors: Billeter[5] has tested surgical material of the clinic of Professor Krönlein and subjected the postoperative history of 116 cases that were operated on for ulcer of the stomach to a most thorough critical investigation. They were cases that were operated by Krönlein from 1888 to 1910. The shortest period of time that had elapsed was four years, although some were seen 26 years after the operation. The operations were simple gastroenterostomies (not excision). Of the total number seen, 19 died, but 87 patients are still living without any sign of carcinoma. Of the 19 patients that died only 2 suffered from gastric carcinoma. Only one of these cases, however, was secondary, the other was a primary cancer. This one showed a cancer of the omentum, that had developed from a primary cancer of the stomach. In ten patients in which there was a suspicion of cancer of the stomach during operation, complete recovery resulted. *So in the total number of* 116 *cases of ulcer of stomach operated, only one reacted with a secondary carcinoma.* According to this investigation, *one is not in duty bound to establish as a therapeutic principle the resection of gastric ulcer on account of any subsequent danger from carcinoma.*

Not every scar in the mucosa of the stomach can be attributed to a previous ulcer, for there are wounds of the gastric mucosa due to trauma by shell pieces from oysters, eggs and fish bones, which never acquire the conformation and characteristic appearance of peptic ulcer. The typical gastric ulcer is in great majority a consequence of obstruction, stasis in, or spasm of one of the terminal arterioles of the gastric artery. The tissue of the territory supplied by this little artery then undergoes necrobiosis and is destroyed by the proteolytic enzyme and the HCl of the gastric juice. The improvised peristalsis referred to as *stasis* above may be due to neurogenic causes (vagotonia). Ernst Adolf Schmidt[6] has made clear to us how an abnormal, deranged and impaired peristalsis may act as a cause of gastric ulcer.

This digesting dissolution may occur just as *quickly* as that of any other small particle of protein substance placed in active gastric juice, *i.e.*, in a few hours. Carcinomata develop, as a rule, when there is a very defective gastric secretion or none at all. The disintegration of a cancer is due to an autolysis by enzymes inherent in the neoplastic cell. Physiologic and chemic tests indicate that these cancer enzymes are not near as active, nor even so continually present, as HCl and pepsin in gastric ulcer. Hence a cancer must require a much longer time to disintegrate, to resemble the form of any ulcer, than it requires for the development of a typical peptic ulcer. Only such losses of gastric substance should be termed peptic ulcers which in addition to a characteristic clinical history present also the typical funnel-shaped appearance and the terracing of the ulcer bed, which, as I stated, is due to the nature and form of distribution of the supplying artery that is in some way obliterated. To assume that disease of the supplying artery is the immediate cause does not necessarily exclude disease of the vagus (excessive vagotonus), or even the action of the toxins (for example, toxins absorbed from skin burns or the sepsin of Edwin S. Faust) of a purely chemic or bacterial origin, for all of the neurogenic or chemic causes may lead to spasm or disease of the arteries of the stomach.

If scars are blamable always as causative of cancer, I fail to understand why the scar left after excision of an ulcer should not also be considerered as an etiologic factor. I have frequently observed scars in the stomach of patients at autopsy, the authentic clinical record of whom gave the history of typical gastric ulcer for many years previously. In some of the most accurate records 18 to 30 years had, in individual cases, elapsed between the period of clinical signs and symptoms of gastric ulcer and death, due, not to any consequence of ulcer, but to intercurrent other diseases (pneumonia, accidents of puerperium, septic infection, etc.). Evidently gastric scars can exist for 20 to 30 years without giving rise to cancer.

Synopsis.—Personal cases studied from 4 to 25 years after medical treatment—614 total number.

Two hundred and thirty-two cases treated medically from 1884 to 1910 and either personally reexamined or examined by reliable physicians and reported by them. Of these 232 only three gave a history of operations for carcinoma.

The following are the questions which were submitted to each physician who was in charge of my patients at the time this investigation was made:

What was your body weight before the operation, and now?

What was the previous history?

What has been the clinical history since the operation?

What is your general condition?

What are the results of examining the functions of the stomach secretions, peristalsis, and absorption?

Have you eructation, vomiting, pains in the stomach, hematemesis?

Have you ever been under medical treatment since the operation?

By whom? What was the diagnosis? What did you complain of? Send the opinion of your physician.

In view of the arguments presented by Billeter in the preceding, and secondly based on the statistical studies from German cities, and thirdly on my own personal experience extending over twenty-five years, I am of the opinion that whilst ulcer of the stomach may be a possible cause of cancer, it is a rare cause. In Billeter's experience not over once in 116 cases of ulcer of the stomach, and in my own experience, three cases of cancer in the later history of 232 cases of gastric ulcer observed during twenty-five years.

CARCINOMA OF THE STOMACH.*

BY JOHN F. ERDMANN, M.D.,

NEW YORK.

IN 1911 I reported in abstract a series of cases of malignancy of the stomach, with excision, since which time I have removed the greater portion of the stomach for malignancy in thirty additional patients. Pylorectomy for benign conditions was done in quite a number of patients. As this subject deals with malignancy, no note will be taken of the non-malignant excisions.

Palpable tumor is not a non-operable entity—in fact, palpable tumors are frequently more operable than those not palpable—but a palpable tumor is then a case of sufficiently advanced malignancy to modify our preoperative prognosis as to extension of life. A palpable tumor is to-day not the essential to diagnosis as formerly. To-day the *x*-ray, while not positive in all patients presenting carcinoma, is nevertheless quite an aid in diagnosis and a means, frequently, to an end in diagnosing malignancy quite early. Again, an apparently fixed tumor on palpation may be justifiably operable in the fullest sense of the word—that is, removable with a fair show of non-recurrence, due to the fact that many of these tumors are fixed by adhesions primarily due to inflammatory exudates. Again, removable from the standpoint of low mortality and definite extension of life, with freedom as to recurrences from months to years.

These statements, while possibly strong, are borne out many times in operations. Again the tumor, its fixity, and the general condition of the patient must be considered as factors to prevent at least exploring the abdomen. Furthermore, the apparent site of the gastric tumor, with relationship to the surgical zones of the abdomen, should not retard our suggesting exploration, as a tumor of the pylorus, etc., is often so free, by means of its long attachments, as to allow great excursions of the affected part to the zone usually occupied by the greater curvature, etc. Again, the tumor may occupy the central portion of the stomach, with a perfectly free or patent pylorus—simulating thereby, in its area of occupation, the greater curvature of the stomach or even its fundus.

Adhesions to the pancreas, necessitating removing a thin slice of this organ, are also within the pale of operative procedure with perfect success. In my first report, I sliced the top of the pancreas twice in fourteen patients, with recovery in both. This procedure was carried out in several of my later thirty patients.

I have removed the transverse colon four times with the stomach; three of these were for metastases or contiguous involvement, while the fourth, my first transcolectomy, was due to an injury—operative infliction, to the colica media. The last patient, from whom I removed the entire transverse colon and four-fifths of the stomach en masse, was a youth of twenty-seven years, with recovery. This case will be reported clinically in the *Annals of Surgery*, under the transactions of the New York Surgical Society, for March, 1915.

If we wait for all the diagnostic factors, signs, etc., of carcinoma of the stomach to be present, we can then operate only upon patients presenting a palpable tumor. Unfortunate as this statement is,

*Read before the Medical Association of the Greater City of New York at Forest Hills, April 5, 1915, and the Plainfield Clinical Society at Plainfield, N. J., April 20, 1915.

it carries with it the argument that our analyses of symptoms and stomach contents are yet at fault for the rendition of a perfect diagnosis. Again, this indefiniteness in many patients is the frequent reason given for not urging an exploratory operation.

This leads me to quote Graham, of Rochester: "The satisfaction that may follow an exact diagnosis does not justify us in prolonged observation. The chief factor to be considered is what we owe the sufferer." As a result of exploration we are in a position to relieve the anxiety of the patient and his family, if the result be non-malignant; and to relieve him of his vicious and undesired tenant or to modify his suffering, should the result be malignant.

Being aware then of the indefiniteness of the symptoms of this disease in a fair percentage of the patients coming to us for diagnosis and treatment, and receiving doubtful or indefinite assistance from the physiological and chemical laboratories, in the same proportion, in justice to the patient, to ourselves, and the family physician we must demand, in this percentage of applicants for relief, exploration.

There is great possibility of carcinoma being present in the patient who complains of stomach difficulty for years; who gives a history of having had ulcer of the stomach some years previously, or even an active ulcer history at the time he presents himself.

Then we must consider the food intake pains; vomiting of food one or more meals back, *i.e.* retention or cumulative vomiting; blood in the vomitus; blood in the stools; loss of weight; rapid diminution of hemoglobin; marked prostration, etc.

Rectal examination should be made in all suspected patients for Blumer's shelf. This condition, described by Blumer of Yale, consists of a sharp shelf-like process just above the prostate; felt on digital examination in the male; and a process in the female about the cervicocorporeal portion of the uterus in Douglass' cul-de-sac. This shelf is due to a secondary deposit or metastasis. When this process is present it predicates futility as to an operative result and should condemn operative procedure.

The various food tests, by which we gain a knowledge chiefly of stagnation and obstructive retention, should be sought for in the history, and frequently this information is volunteered by the patient while giving his history.

The chemical analyses, while not of the great importance assigned by many, nevertheless are important factors when considered in the general symptom complex. Thus, absence of free hydrochloric acid and presence of lactic acid are very strong factors in enabling us to arrive at a conclusion. It must be remembered that hydrochloric acid may be present even in excess in carcinoma, and particularly so in those patients in whom we find a former gastric ulcer, with carcinoma as a direct resultant. This type of carcinoma has been rated as being found in from 40 to 60 plus per cent. by various authors; hence the patient who gives a history of ulcer of the stomach extending over a period of years is a suspected, if not already, cancer subject.

The patient, whose stomach findings include the Opler-Boas bacilli, is, as a rule, one with marked carcinoma development. The very presence of Opler-Boas bacilli, although indicating as above stated, "distinct or marked carcinoma," does not, by far, preclude the patient's being in the operative class. Unfortunately, the carcinomata involving the cardia are at present most discouraging lesions to the operator, as here we have not only the difficulties of the position as to operative feasibility to overcome, but also the high mortality accompanying the various types of operation performed at the present time, necessitating prolonged anesthesia under various pressures, and also in the majority requiring a transpleural route.

With the low mortality rate attending so serious an operation as partial gastrectomy, one naturally would or should prefer the operative risk, with an outlook of from a year's relief to a cure, in preference to retaining so undesirable and vicious a tenant, with the continuous and increasing suffering and the positive outlook of death, if not removed.

Age has no bearing upon the possibility of a persistent gastric illness being carcinoma; I would state that of forty-four excisions four were under twenty-nine years of age; the youngest had just passed his twenty-sixth birthday.

In observing the patients after gastrectomies, one is impressed with the absence of shock, and also with the response that these patients make. The recovery is exceptionally speedy and may be attributed to numerous causes, as cessation of hemorrhage; removal of sloughing, ulcerating areas—thereby checking the absorption of toxins produced by these processes; the proper emptying of the stomach, etc., etc.

The after care of these patients is not more difficult than in an ordinary gastroenterostomy. Personally, I allow these patients water after twelve to twenty-four hours, in one to two ounce doses; this is followed or alternated with albumen water or strained broths; on the second or third day, broths and milk; on the fourth and fifth, selected softs or semi-solids; and on the eighth and ninth, selected or ordinary diet. This type of patient craves food from the moment his stomach is at rest, following the operation, usually at the end of the first twenty-four to thirty-six hours.

It may be necessary to wash the stomach during the first twelve to twenty-four hours for acute dilatation, etc. No hesitancy for doing so should occur. Careful introduction of the tube and four to six ounces of fluid used, has not met with a single accident in numbers of such instances, either in excision or in simple gastroenterostomies.

Operative Procedure.—Under the head of radical removal one considers any of the various types of resection of the stomach commonly performed, chief among them being the Billroth No. 2 operation, partial gastrectomy with pylorectomy—adding to it, of course, the necessary posterior gastroenterostomy.

This operation, at the present date, has been modified very much by Polya and Reichel (see *Progressive Medicine*, pages 93-94, June, 1912), who published their methods some three or four years ago. This operation was very ably described and illustrated by Dr. Will Mayo, in a recent issue of "Surgery, Gynecology and Obstetrics."

The method of procedure in the Polya operation is as follows: The duodenum is severed after the usual fashion between clamps; the distal end turned in; the stomach is excised, going well beyond the malignant process. Instead of doing the closure of the proximal end of the stomach, as in the Billroth resections, Polya made a direct anastomosis between the jejunum and the proximal end of the stomach, doing away thereby with the added pos-

terior gastroenterostomy. After the stomach has been excised, the proximal portion, or the remaining part, in other words, is anastomosed by first of all attaching to it the jejunum, which has been passed through a rent in the transverse mesocolon in the same manner as the jejunum is passed through it during the ordinary gastroenterostomy. The jejunum is sewed to the posterior wall of the proximal end of the stomach, within a quarter or half inch of the point at which the clamp used in the excision has been placed. After the peritoneal apposition suture has been completed, the clamp on the proximal end of the stomach is taken off, and the jejunum is opened in line with the stomach, extending practically the full length of the width of the stomach—having previously applied clamps to the jejunum and stomach to prevent soiling. Should the length of the stomach opening be far greater than one desires to open into the jejunum, then the sewing together of the end of the divided stomach and the opening of the jejunum is accomplished by shirring the edge of the stomach, suturing so as to take in more of the stomach wall in each suture bite than is taken in the walls of the jejunum. The subsequent rows of sutures and apposition of tissues are made the same as one does in doing a posterior gastroenterostomy. Subsequent to the anastomosis, the stomach is sewed to the rent in the transverse mesocolon. This operation obviates, as before stated, the making of an additional posterior gastroenterostomy and limits the operation considerably in duration—in addition to limiting the operation in duration it also limits the exposure of the peritoneal cavity to infection; again, it limits the possibilities of hemorrhage by one-third.

I am quite satisfied that, after this operation has been tried by the general operator, he will forego all previous types of anastomosis between the jejunum and the stomach in this and other conditions requiring excision of the stomach.

Palliative operations are those operations which are performed where the conditions found at the time of the exposure of the abdominal contents are such as to prevent one continuing the radical operation, as: excessive glandular involvement; excessive wall involvement; fixation, etc., etc. These operations consist of either a gastroenterostomy, anterior or posterior placed, or a jejunostomy.

Anterior gastroenterostomy is done in those instances in which the stomach cannot be rotated sufficiently to place a posterior gastroenterostomy in healthy tissue. I am of the belief that all cases in which a posterior gastroenterostomy can readily be performed should be subjected to an excision. Anterior gastroenterostomy is also done in those instances in which it is absolutely impossible, owing to the conditions of the stomach wall, to resect or do a posterior gastroenterostomy, and also in those patients in whom the condition as far as physical outlook is concerned would negative a resection.

This operation may be performed either by slipping the loop of the jejunum up through the entire transverse mesocolon and attaching it anteriorly, or by making a long loop, anteriorly, and placing it in direct contact with the stomach wall—adding usually an enteroenterostomy to prevent a vicious loop.

Jejunostomy is an operation which is very prone to be followed by very pronounced leakage, no matter what care is taken. These patients as a rule are very markedly emaciated and in an exceedingly poor physical condition. It is an operation that I have heretofore looked upon purely as one for euthanasia, except one considers that now and then a tumor, apparently inoperable, is likely to prove largely inflammatory or irritative, and is imposed upon a small carcinoma. By means of a jejunostomy the patient's condition may improve markedly, and a subsidence of the inflammatory or irritative material occur to such a degree that a radical removal might be possible.

I fear that many of us, as operators, have not been giving the full benefit of the radical operation to our patients, because we fear an added mortality, or because we feel that we are not sufficiently developed in our surgical technique to cope with the conditions that are found.

I am quite sure that at the present date I am accepting for radical removal more and more stomachs which, in my earlier days, I would have looked upon with a great deal of question as to whether or not I should do but a palliative operation or close the abdomen without any visceral operative procedure.

60 West Fifty-second Street

A PLEA FOR THE RATIONAL TREATMENT OF CANCER.

By L. DUNCAN BULKLEY, A.M., M.D.,

NEW YORK,

SENIOR PHYSICIAN TO THE NEW YORK SKIN AND CANCER HOSPITAL, ETC.

Many cases of undoubted cancer, both primary and recurrent after operation, are on record which have disappeared entirely and remained absent under a complete change of diet and mode of life, with more or less of proper medical treatment. Multitudes of cases are known everywhere in whom the disease has recurred, with terrible severity and death, even after the most complete removal, by the most competent surgeons, of very early lesions diagnosed as cancer, some of which proved to be only adenoma, microscopically.

The enormous mass of laboratory studies which have been recorded has added thus far very little to our knowledge of the real nature and cause of cancer, and really nothing to treatment, except to advocate the surgeon's claim of the right to remove instantly everything suspected to be cancer or "precancerous"! Surgery has striven, more and more actively of late years, to stem the rising tide of mortality from cancer, but, alas! the Mortality Tables of the United States show the futility of this means, for the death rate from this disease has risen over 25 per cent. since 1900.

Laboratory researches have rendered, however, a valuable service in connection with cancer, by the negative results obtained, so that the ground is pretty well cleared for a proper understanding of the real nature and cause of the disease. Thus, all are pretty well agreed that cancer is *not* due to a parasite, *nor* contagious, that it is not strongly hereditary, *nor* due wholly to local irritant action, that it is *not* altogether a disease of old age, *nor* belonging to any particular occupation, and that it does *not* affect any special sex, race, or class of persons: cancer exists all over the earth, but with striking differences in frequency, according to certain peculiarities in diet and mode of living, associated with advancing civilization.

The exclusion of the various suspected causes of cancer by the prolonged study of many trained

laboratory and other workers along the lines mentioned leads the thoughtful person to inquire if there is not still some line of possible etiology which has not yet been fully explored; for assuredly there is some actual, physical cause for the aberrant action of originally normal tissue cells, which we call cancer. There is nothing mysterious about the disease, except that thus far its real cause has eluded laboratory workers, but which clinical workers have long suspected and suggested without much, if any, effect on the profession, so enamored has it become of surgery, and so insistent and loud have been the claims for a wholly local origin and nature of the disease.

But the failure of surgery to make any appreciable effect on the morbidity and mortality of cancer, as already mentioned, and the exclusion of all other possible causes, naturally leads us to look to a faulty metabolism, which has to do with such a multitude of other human ailments, and the deeper we search the laboratory and other studies which have been made regarding this, the more clear does it appear that it is along these lines we shall find the true means for the prevention and cure of cancer.

It is quite impossible in a brief article to present the evidence in which this statement is founded, which has been developed pretty fully elsewhere,* and it must suffice to concisely state the principal points.

Cancer has been found definitely to increase with the spread of modern so-called civilization along the lines of luxury and attending indolence. This has been observed especially in the over-consumption of meat, coffee, and alcohol, as proven by statistics.

Many have recorded changes in the urine which indicate imperfect metabolism, especially of nitrogenous matter. Careful daily studies of the urine, both in the very earliest stages of cancer and late in the disease, show a very marked failure of elimination by this excretion, the solids being often not one-half of that called for by the body weight of the individual. Careful observation will also detect a great failure in intestinal elimination, in both the very early stages of the disease and all through its course. So true is this that Sir Arbuthnot Lane has declared that cancer may be one of the late results of intestinal stasis. This probably operates through the poisonous action developed by the millions of microorganisms formed in the large intestine, indican being not an infrequent urinary exhibit. It has been shown that cholesterin is also an important element in connection with the genesis of cancer, and there is strong evidence that derangement of the endocrinous glands is associated with the production of this disease.

It is quite true that the exact metabolic disturbances, or the actual blood state, inducing and perpetuating cancer, have not as yet been demonstrated, and perhaps they never will be. But it has also never been shown exactly how cancer begins, or when a benign tissue becomes malignant, as Ribert has said "no one has ever seen the beginnings of mammary cancer": both aspects of the question, the constitutional and the local, rest on clinical grounds, and not a shadow of proof has ever been presented that the lump which we call cancer is purely local in character.

On the other hand the constant tendency to a recurrence of the disease in the same or other locations, even after the most complete removal of the local lesion and surroundings, and the continued depression of vitality and degeneration of the blood, all point to something more than a local disease; they all show a constitutional cause which induced the original stasis and degenerative action of tissue in some particular locality which was unduly irritated, probably the site of an "embryonic rest," that is, a heterologous tissue ready to revert to reproductive life. This latter would seem to be the starting point, inasmuch as the tissues in general of cancerous subjects heal kindly, and, after injury on various portions of the body there is little or no tendency to tumor formation.

Even the occurrence of metastases accords also with the view of a constitutional disorder. For after surgical operation the patient is invariably left uncared for, as far as any attempt to alter the dyscrasic condition which engendered the disease, and very naturally the transference of cancerous elements by the blood or lymph stream produces a local condition which the vitiated blood current develops into a fresh local lesion.

The apathy of surgeons to medical suggestions of their own distinguished members, past and present, is very surprising, but not less so than the practical disregard of cancer by physicians. One finds the strongest expressions in regard to the constitutional relations of cancer by Lambe, Abernethy, Willard Parker, Sir Astley Cooper, Sir James Paget, Esmarck, Sir Arbuthnot Lane, and others; and finally Dr. William J. Mayo, in his recent president's address before the American Surgical Association, asks, "Is it not possible, therefore, that there is something in the habits of civilized man, in the cooking or other preparation of his food, which acts to produce the pre-cancerous condition?"

And yet there has been relatively little serious attempt to investigate this line of thought or to test the principles underlying the metabolic theory of cancer, in its relation to diet and mode of life, as influenced by so-called civilization. While the microscope and laboratory work on animals have undoubtedly advanced the science of medicine prodigiously, they seem to have reached their limit in regard to cancer. Their negative conclusions, however, have paved the way for the medical man, through clinical study and physiological chemistry, to reach the real basic cause of the disease in the activities of system as a whole, as influenced by diet and mode of life.

This plea is made, therefore, with the hope that the matter may be thoroughly investigated and tested, and that it may result in a more rational treatment than the present one of attempting only to remove the *product of the disease*, the local tumor, while the cause of the formation of the malgrowth remains still active. Only by a rational treatment of the cause can we hope to restrain the steady increase of cancer, and to reduce its frightful mortality of 90 per cent. of those whom it has once attacked.

531 Madison Avenue.

*Bulkley—Cancer: its Cause and Treatment, New York, 1915.

Osteochondritis Deformans Juvenilis.—Brandes points out that this disease is not identical with arthritis deformans. It affects chiefly the hip. The pathognomonic symptom is the normal degree of flexion of the latter together with a pronounced limitation in abduction. The condition must be differentiated from coxa vara and coxitis.—*Medizinische Klinik.*

ORGANOTHERAPY IN CHRONIC DISEASE WITH SPECIAL REFERENCE TO ITS POSSIBILITIES IN CANCER.*

By HENRY R. HARROWER, M.D.,

NEW YORK.

SOMETIME PROFESSOR OF CLINICAL DIAGNOSIS, LOYOLA UNIVERSITY, CHICAGO; FELLOW OF THE ROYAL SOCIETY OF MEDICINE.

THE treatment of chronic disease, at best too often a difficult and unsatisfactory matter, has been considered by so many physicians so many times that further reference to the subject may seem to be almost out of place, for already there is an overwhelming number of papers and many books concerned with the advantages of all forms of treatment of chronic disease, from the surgical removal of presumably offending organs to the Emanuel Movement, and including other more or less useful methods such as hydrotherapy, electrotherapy, psychotherapy, serotherapy, autotherapy, and, most recent of all, the intestinal short circuit as suggested by Sir Arbuthnot Lane.

The mere fact that disease has been present for more than the proverbial forty days and that a good percentage of chronic invalids perambulate from one doctor's office to another, as well as the suggestion already made that many widely differing forms of treatment are advanced more or less enthusiastically from time to time, seem to be convincing evidence that the treatment of chronic disease is still an unsolved problem and hence worthy of persistent study.

This evening it is proposed to consider another fairly well known phase of therapeutics and to urge its more frequent application to the indefinite and chronic disorders, many of which have not the dignity of a name and others of which are classed, rightly or wrongly, under the name of the principal symptoms, chief among these being neurasthenia. It does not seem advisable, at this stage of progress, to make any hard and fast statements, hence all that may be said here to-night will be purely suggestive, the prospective value of such procedures as may be mentioned being left to the judgment of those who, being convinced of the reasonable basis outlined, may be sufficiently interested to put them to the test.

There seem to be fashions in medical matters just as there are in dress or art. If I am not much mistaken it is beginning to be the fashion to study and write about the internal secretions. A number of books have appeared on this subject. I even plead guilty to having written one on the therapeutics of the internal secretions. There are, without the least exaggeration, thousands of papers on the various phases of this fascinating subject published in practically every quarter, chiefly however in French, Russian, and Italian.

All this is as it should be, for from all sides come words of commendation and evidences of profound interest, and every interested physician that I have had the pleasure of meeting in half a dozen different countries has manifested an unwonted enthusiasm in his investigation of this subject—it breeds enthusiasm, for so often we stumble across the most startlingly wonderful things which when they are first published abroad are usually greeted with the smile of scorn, just as were Roentgen's remarkable rays, or Marconi's equally amazing discovery, or Alexander Graham Bell's wonderful invention, by which all of us have profited so much. Sir William Osler told me only a short time ago when I visited him at Oxford that surgery had been having its innings for the past ten years or more and it was time for medicine to have its turn and probably the "bat" would be the internal secretions of the ductless glands. For instance, what surgical discovery excels in its scope and wonder the many-sided usefulness of pituitary extract?

In these days of advance in physiological and pathological research we have gradually accumulated a fair knowledge of the series of organs which were until recently almost entirely unknown. We have learned that the ductless glands or endocrinous organs exercise an intimate control over metabolism and the cellular activities, that this is in all probability brought about by definite chemical substances produced in these organs and conveyed from them to others by means of the blood and lymph—the "hormones," so named by Starling in 1902—and, best of all, that it is possible to secure from animal glands certain active hormone-bearing substances in a more or less pure state which are available in the treatment of disease.

We cannot stop to consider the occasional statements to the effect that organotherapy is a fad, or that it is still in its infancy and hence not worthy of more than passing consideration, and that much more work will have to be done before the subject reaches a really practical stage. Those who manifest such sentiments invariably make their statements without deliberation and due consideration of the facts. None can deny that certain of the ductless glands produce extremely active principles which have an equally active influence in the control of normal as well as morbid phenomena. We have only to recall the influence of thyroid extract in myxedema, epinephrin in local hemorrhage, or pituitary extract in labor to realize that there are sufficient inducements to delve more deeply into the study of the extracts of these organs, as well as of others known to be concerned in the maintenance of what is now termed "the hormone balance."

This factor deserves much more consideration than it is possible to give it this evening, for the delicate balance brought about by the interrelation of the internal secretions is concerned in the maintenance of essential health none the less than in the production of deviations therefrom. I am going to propound what I believe to be an axiom—it is impossible for an individual to manifest the results of chronic disease without a corresponding disturbance in some or all of these hormone-producing organs. Further than that, I believe that many of these intractable symptoms-complex, to which it is sometimes so difficult to give a suitable name, are often aggravated by a disturbance in what has been termed the "altruistic function" of the cell. I will explain: Campbell considers that cell activity is properly divided into the egoistic and the altruistic cell functions. The former consists in the maintenance of individual cell activity, while the latter concerns the supply to the organism as a whole of certain services, probably brought about by the hormones, such as are exemplified in the numerous functional relationships between organs. This altruistic function is of extreme importance, for the cell itself may seem to all intents and purposes quite healthy and yet still gravely fail in its altruistic functioning—a failure which, small though it be, may suffice to disorganize the delicate hormonic

*A paper read before the Medical Association of the Greater City of New York, February 15, 1915.

balance. Granting, then, that chronic disturbances are associated with general cellular inactivity and that in certain conditions this deprives the body of essential stimuli, it must be obvious that the effective treatment of such conditions must include a consideration of the ductless glands and of means capable of reestablishing the normal production of these essential chemical messengers.

One of the most common disorders in which so-called "pluriglandular insufficiency" is evident is neurasthenia, in which there may be no positive evidence of defective action of a gland or series of glands. It is obvious that in the majority of such cases there must be a disturbed endocrinism, for it is hardly reasonable to suppose that in an individual with prominent manifestations of half-speed function, such as constant fatigue on slight exertion, defective oxidation as evidenced by low urinary solids, nerves that are easily set "on edge," circulation that is poor, with cold, clammy extremities, and not infrequently reduced tension, ambition and mental powers much below par, and the like, the production of the essential chemical messengers is not reduced just as are all the body activities. This being the case, pluriglandular therapy not only serves to replace, in however slight degree, the missing secretions, but favors an increased production of them by the homostimulant action already referred to.

Theoretically this sounds very plausible and practically it has been found to work very nicely. Pluriglandular therapy is undoubtedly empirical, for in the class of cases under discussion at least, there is no definite proof as to which of the ductless glands is deficient and to what extent. For this reason it has been ridiculed by some who forget that nine-tenths of our present therapeutics was at one time purely empirical, while a good share of it still has no positive scientific basis. A procedure that has secured results before may do so again, hence it is worth trying. This is the present position of pluriglandular therapy, and it is believed that the successes already obtained are an earnest of what is in prospect.

Another important series of chronic conditions which must at least be mentioned in passing are the functional neuroses and psychoses, many of which are now earmarked as resulting from or being intimately associated with disorded secretory action of certain of the ductless glands. In a recent paper in the *American Journal of Insanity*, Murray Auer concludes that the glands of internal secretion mutually influence functional activity and the occurrence of insanity at puberty and adolescence, after severe physical and mental strain, and at the time of the menopause (all periods when the metabolic changes of the body are intense), and the occurrence of syndromes unquestionably the result of disease of the endocrinous organs, insanity, idiocy, debility, mania and dementia, suggest strongly that the true etiology of the affective psychoses lies in functional disturbances of the glands of internal secretion.

Many of the problems of the medical gynecologist have a purely endocrinous origin, and the metabolic disturbances of women constitute a large class of chronic diseases in which organotherapy is an extremely useful measure. Substitutive organotherapy is an every-day measure of the most progressive gynecologists and the subject is far too large to discuss here. The value of the extracts of the corpus luteum in ovarian hypofunction, as well as the homostimulant action of the same substance in less serious conditions, is becoming increasingly apparent. Pituitary extract is now used in a great many cases of this class, not merely for its obstetrical virtues but as a means of reestablishing a disturbed balance in cases like amenorrhea and certain forms of dysmenorrhea.

One of the most neglected organotherapeutic remedies in gynecological practice is the extract of the mamma, about which I cannot refrain from saying a few words. Briefly, the mamma is also an internal secretory organ and is the direct antagonist of the ovaries, hence extracts thereof may be of value in the control of conditions due to superactivity of the ovaries. The principal among these are menorrhagia, metrorrhagia, and uterine fibroids. I know the surgeons will disagree, but the fact remains that functional uterine hemorrhage (not due to foreign bodies or organic conditions) is frequently controlled better by a course of mammary extract than by any other means and there is a rational physiological reason for this benefit. A number of Russian investigators have shown that the use of mammary substance is of extreme value in many cases of fibroids and those who may be especially interested in this subject might with advantage read a paper which I have prepared for a Special Internal Secretion Issue of the *Woman's Medical Journal* for March, 1915. Suffice it to say that enough evidence is gathered together there to warrant the use of mammary extract for a period before operative procedures are taken and the aggregate results are sufficiently good eventually to bring this method of treatment into much higher esteem and frequent usage.

You will note that I have said nothing about the use of thyroid extract in the chronic and well-known conditions associated with thyroid deficiency, nor can I take time to outline the advantages of pituitary extract in those equally chronic conditions of hypopituitarism. In fact, organotherapy is principally useful in chronic disease, anyway, and to consider the matter as thoroughly as the subject deserves would keep us here for weeks.

We now come to the second and perhaps the more important part of this paper—the relation of the glands of internal secretion to cancer and the possibilities of organotherapy in this condition. This is neither the place nor the time to discuss the physiological basis of cancer or to speculate upon the how or why of this disease. We may, however, enumerate several promising and quite thoroughly substantiated theories: (1) Cancer is a chronic intoxication; (2) its incidence evidences the lack of an element in the blood which permits cell proliferation at a point of particularly lowered resistance; (3) it is essentially a disease of senescence or, as Hastings Gilford has termed it, "cell senilism."

Seven or eight years ago many hopes were raised following the publication of the results of work done by Dr. John Beard of Edinburgh, and quite an impetus was given to the study of organotherapy in cancer because of the fact that trypsin was then brought forward in medical and, unfortunately, lay magazines as "worthy of immediate trial in the behalf of the many persons to whom it offers a possible chance of escape from an otherwise inexorable fate." Seemingly the attention of the public was drawn prematurely, for there has been no remarkable reduction in the mortality statistics nor do any of us here consider that pancreatic ferments are more than an incidental measure of relief in cancer.

It must be admitted, however, that Beard's work

virtually inaugurated a more enthusiastic and searching consideration of organotherapy in cancer and while we have advanced many steps since 1905 we must not be satisfied yet. In the words of a recent writer: "We have survived too many hypotheses in regard to this elusive disease to accept further generalizations however plausible they may be at first inspection of the evidence; yet we are always glad to recognize every scintilla of a new suggestion which may furnish a welcome guide to progress."

With the foregoing in mind it may be well to collate a number of ideas which indicate a relationship between the incidence of cancer and ductless gland disorder, so that we may use them as a foundation for possible lines of treatment in this direction. They may also serve as a basis for explaining the not infrequent reports of the good results from organotherapy in cancer which are to be found in the literature.

We know that cellular activity is influenced by the hormones, or chemical messengers, that nutrition responds in a greater or lesser degree to their influence, and that it is possible to favor the reaction of the body against disease by the ingestion of certain organic extracts. The first question which naturally suggests itself is: Is not cancer more than a chronic disease such as the more benign metabolic disturbances previously referred to? Is it possible to influence by means of organotherapy an unquestionably organic condition when the action of the endocrinous principles is supposed to be upon function rather than upon structure? Undoubtedly no form of internal medication at present known will destroy or remove the fundamental organic conditions pathognomonic of cancer, but it is entirely possible that the resistance of the sufferer from cancer may be increased to such a degree that other measures in common use may be backed up by an increase in the responsiveness of the cells and a general enhancement of nutrition.

Some individuals, for reasons at present only premised, present a special receptivity to the implantation and growth of cancer cells. Why this should be so and just how the cells become implanted is not for us to consider here, although it is a very fascinating subject and will, I believe, some day be thoroughly elucidated. I think it will be found to be much more intimately concerned with the internal secretions than is at present generally believed.

Clinically, the one essential symptom of cancer is waning cellular activity. Almost invariably nutrition is poor and with few exceptions cancer is limited to individuals past the prime of life, a fact which indicates there may be a direct connection between the activity of those organs of internal secretion whose work ceases at this period and whose action is no longer needed. Experimentally it seems to be proved that there is a basis for the idea that the susceptibility to the implantation of the cancer cells is in some way related to the gonads and evidence of this is to be found in the investigations of Sweet, Corson-White, and Saxon of Philadelphia, who found that when tumors were transplanted into animals (mice) which had previously been castrated the frequency of the establishment of the cancerous implant, as well as the rapidity of its proliferation, was much more noticeable in the animals thus rendered more susceptible.

If we admit that an important factor in all cancer cases is chronic cellular intoxication, then obviously a part of the treatment consists in favoring the activity of the known detoxicating organs as well as removing all nidi of further trouble, chiefly, of course, in the alimentary canal. The thyroparathyroid apparatus is intimately concerned in the destruction of toxins and it is not remarkable to find a number of references in the literature to the fact that in cancer subjects the thyroid is usually found to be more or less atrophied. Parenthetically, it may be remarked that thyroid hypofunction is very much more common than until recently has been believed, and it is entirely possible for the thyroid cells to be seemingly normal from a pathological standpoint and yet be failing very materially in the production of those substances which are responsible for the carrying out of the "altruistic work" of this gland. Of course there has been considerable opposition to any theory which definitely connected the thyroid with this disease for thyroid therapy will be found to have practically no influence at all upon cancer.

The association of intestinal fermentation, however, has long been observed in cancerous individuals and has even formed the basis of several theories as to its etiology. One of the well known manifestations of the cancerous cachexia is achlorhydria and the resulting digestive disabilities. For this reason I recommend as a reasonable organotherapeutic procedure in all cases of cancer the attempt to reestablish the activities of the digestive glands by the administration of secretin. This alimentary hormone, secured from the duodenal walls, is a physiological means of stimulating the functionally inactive glands of the pancreas, liver, and intestines. Another sound reason for this particular adjunct measure lies in the fact that the absence of HCl from the stomach removes the normal stimulus to secretin production, since prosecretin is converted into secretin and released from the duodenal walls only by contact with the acid chyme, which is practically always absent in cancer. Further, since the action of secretin is not limited to the digestive glands themselves, but also distinctly favors the production of secretin in the duodenum itself, its value should be doubly evident, and the advantages accruing from the enhanced digestion resulting from this procedure reduce the toxemia normally present in cancer and at least must be considered one factor, even though a small one, in the treatment of this disease.

The second of the postulates previously set forth suggests the absence from the body of a certain element, or series of elements. Just what is missing from the blood of the cancerous is not yet well known, although the work of Abderhalden and those his research has stimulated indicates a definite series of substances may be concerned in this matter. Weiss has gone so far as to show that serodiagnostic tests demonstrate an opposite behavior on the part of the serum from cancer patients and normal serum, and that this definite lack permits cancer cells to proliferate, principally at parts exposed to mechanical stress or irritation. He even suggests it may be possible to isolate from normal serum the element in question, the lack of which permits malignant proliferation, and utilize this in the prophylaxis and treatment of cancer. However near this may be to the truth, it will obviously be an extremely difficult matter to make practical use of it, at least to any considerable extent, and we must look still further for encouragement. This missing element, to my mind, will likely be found to be produced by the endocrinous system, and, since the

evidence already deduced indicates that this is not an unreasonable premise, the therapeutic possibilities are materially increased, for we now know with considerable certainty that when there is a functional hypoendocrinism or reduction in activity or service to the body of certain of the internal secretory organs, not only can the missing substances be replaced, but the semi-active organs may be stimulated by certain organic extracts in accordance with Hallion's law of homostimulation: "Extracts of an organ exert on the same organs an exciting influence which lasts for a longer of shorter time. When the organ is insufficient it is conceivable that this influence augments its action and, when it is injured, that it favors its restoration." Resulting from these and similar premises quite a number of attempts have been made to use organic extracts alone and in various combinations as a part of the treatment of cancer. While we have not yet found an ideal remedy, it seems certain that organic extracts do produce beneficial results of varying degree.

The spleen and thymus offer probably greater possibilities than many of the other glands, although I think that eventually the optimum preparation will be a pluriglandular extract containing these and other synergists. The therapeutic administration of spleen extract increases nutrition, of that I am quite convinced, and those who have followed the work of Bayle of Cannes in the use of spleen emulsions and extracts in the treatment of tuberculosis cannot but be convinced that there is good reason for his success. His report to the International Congress on Tuberculosis in Rome is extremely interesting. I have personally had a number of communications from this gentleman, as we have for some years been mutually interested in each other's work, and when the war started he was engaged in translating my book into French.

Bayle's explanation of the sometimes remarkable influence of spleen extract is based upon what he calls its "colloidogenic" action. His theory is this: The blood contains the mineral elements in two forms—(1) Those in a colloid state suitable for cellular appropriation, and thus not suited for elimination by the kidneys, and (2) the mineral cellular wastes, which are dissolved in the plasma, and are destined to be eliminated. If the colloid elements lose their colloidal form they are promptly eliminated and a condition of demineralization obtains. The capacity to maintain the mineral salts in a colloidal state is evidently of considerable importance, and, according to Bayle, seems to belong to the spleen. Bayle states that he has always found that splenic opotherapy quickly reduces an excessive elimination of phosphates in the urine. All of this deserves to be tested experimentally and clinically.

Now, there is undoubtedly a condition of mineral starvation in all cachectic states, including that of cancer. This has been frequently mentioned in the literature, and is referred to in an editorial in the *Journal of the American Medical Association* in the following words: "This is, however, little less than the metabolic story of partial inanition which attends the cachectic states which accompany so many chronic diseases. The demineralization, that is, the gradual and undue loss of all inorganic elements from the organism, is likewise not to be regarded as characteristic of cancer alone." This is admitted, for one of the principal manifestations of tuberculosis is this very condition, which explains Bayle's suggestions and his successful application of splenic-opotherapy in the treatment of tuberculosis. There is no reason, however, why the same fundamentals should not be applicable in the therapy of cancer as of tuberculosis, and this may be an explanation of the good results occasionally reported from the use of spleen extract.

Another gland frequently classed with the spleen, or at least with the lymphatic glands, is the thymus and more clinical work seems to have been done with thymus extract in cancer than with any other single extract. In 1907 Dwyer reported a number of cases that were benefited by this form of treatment and the more recent experimental researches of Rodenburg, Bullock, and Johnson, of this city, seem to prove that the products of the ductless glands are destined to play a certain rôle in our fight against cancer, and their recommendations include the use of thyroid, thymus, and other extracts as part of the treatment.

Some very interesting work in the study of cancer has been done by Dr. Seelye W. Little of Rochester, N. Y., and as a result of this he outlines certain facts which he has inferred from quite a number of clinical experiences. In the main his contention is that the reproduction of the reverted cell types in cancer is caused by the relative hypofunction of certain of the ductless glands and that to produce a cancerous growth such hypofunction must be primarily in an internal secretory organ derived from the same blastodermic layer as are the cells from which the cancer originates. As a result of this he suggests that mammary carcinoma implies hypofunction of some endocrinous organ derived from the ectoderm, since the breast is ectodermic in origin. He has also shown that the metabolism of sugar and calcium are intimately connected with the disordered nutrition of cancer and connects this in a very convincing manner with those glands which exert a vital relation to the metabolism of sugar or calcium or both.

Little's experiences are fascinatingly outlined in his papers published in the *Boston Medical and Surgical Journal* last year, to which the careful attention of every student of this subject should be drawn. His clinical findings warrant the use of several organic extracts, principally from the pituitary, parathyroid, adrenal cortex and the islands of Langerhans. In his most recent paper, in addition to emphasizing the value of sugar feeding in many cases of cancer, he has settled down to three ductless gland extracts as essential, one each for ectodermic, mesodermic, and endodermic cancer. For the first he uses total pituitary extract; for the second an extract of the adrenal cortex; and for the third an extract of the pancreas rich in the islands of Langerhans. All through his communications there is an underlying element of judicial research. He is not ultra enthusiastic and does not claim to have discovered a panacea for cancer. One cannot but believe from the clinical results of his work that he is on the right track and that the conclusions which may be drawn from some of the facts gathered together here this evening warrant the continued investigation by a much larger number of students of the subject, not only of the relations of the ductless glands to the incidence of cancer, but the use of various preparations of this nature in both prophylactic and direct remedial treatment thereof.

The third essential concerns the relation of the incidence of cancer to senility. We cannot deny that senility is the result of changes in certain of

the internal secretory organs and that by far the greatest cancer incidence will be found in individuals well past the apex of vital activities. Just as fungus growths are usually found on decaying trees, so the similar cancerous manifestations are evidences of senile decay. Dr. Hastings Gilford of Reading, England, writes occasionally on the various subjects connected with senility and the ductless glands, and while at times he delves deeper than I am able to fathom, he is undoubtedly correct in his theories regarding cancer, that it is essentially a form of cell senility. He says that "certain somatic cells become dead while the tissue around them is still in a state of comparative youth. They express their senility by returning to a more embryonic form and as they do so they increase in number, the faculty of proliferation being one of the manifestations of regression." We cannot go into the complex subject which this opens up. Suffice it to say that these senile changes may be presumed to be connected with disturbances in the hormone balance.

This brings us to the consideration of another important phase of this subject—whether it is possible to use these organic extracts as prophylactic agents. I think it may be, but it is very difficult to know how and when to begin, for usually patients suffering with cancer do not give us the opportunity of investigating their trouble until the disease is well established.

Dr. Robert Bell of London has written telling "How to Destroy the Cancer Scourge," and aims to do this by restoring the vital energies of the whole cellular structure by what he considers to be a suitable diet. Unfortunately, however, recourse to this diet does not seem to have become the fashion yet, and the scourge is not being destroyed. The cancerous individuals are always run down; they are in a state of receptivity to disease and are obviously sufferers from pluriglandular insufficiency. If this subject is more carefully studied—it is remarkable how extended are its ramifications and how practical are the resulting clinical deductions—the reasonableness of the pluriglandular therapy will be imminent. In the Special Internal Secretion Number of *The Practitioner* (London), published in January, I had the pleasure of contributing an article on "The Incidence and Treatment of Pluriglandular Insufficiency," and will quote from it a paragraph which has a bearing upon this subject:

"The advantages of pluriglandular therapy are essentially the advantages to be derived from the individual substances which are combined. Obviously such combinations are made with their synergistic action in mind. I have personally used small doses of antagonizing extracts with good results, because it seems that each of the substances stimulates the corresponding organs, thus increasing the hormone content of the blood as a whole and strengthening the chemical messages which are of such vital importance. A point worth emphasis concerns the capacity of the individual organ to respond to the stimulus of the corresponding extract. It seems established that 'the degree of stimulation exerted by the administration of the hormone-bearing substances is in direct ratio to the need for such stimulation, *i.e.* an extract is more efficient when a corresponding active principle is deficient in the body than when present in normal amounts. Hence in a combination of several extracts the principal action is the one which is deficient; that is to say, the more it is needed, the more useful it is.' "

In other words, suitable combinations of glandular substances may be given empirically where a more or less obvious deficiency is presumed. In such cases pluriglandular therapy is helpful whether they may be in the cancerous or even precancerous stage, and such procedures eventually will attain a much more extended usefulness. The whole subject is of fascinating interest and of undoubted practical value and therefore deserves to be studied with renewed vigor now that the subject of the internal secretions and hormones is beginning to receive the attention that its importance deserves.

880 West 180th Street.

THE *X*-RAY IN CARCINOMA OF THE BREAST.*

By MULFORD K FISHER, M.D.,

PHILADELPHIA.

A PAPER on the subject of the Roentgen treatment of carcinoma of the mammary gland in this day should be rightly prefaced by an apology. For the presentation of anything that is new by this method is not the province of this paper; in fact, but little has been advanced in recent years on the subject that is not a rehash of the older procedures. As to the treatment itself, its place as a therapeutic measure after extirpation of the gland is too well known and its employment followed as a routine method to justify a defensive attitude as to the undoubted value of the *x*-rays.

I have endeavored to include in this paper only personal experiences in using the *x*-rays as a routine postoperative measure in mammary cancer, reporting only such cases as have been under my observation at a period previous to three years. In other words, in seeking material and making compilations for this series, I have only included such cases as were operated on previous to December 1, 1911, and in whom a radical operation was performed, followed by routine *x*-ray treatment. Perhaps three years is too conservative a period of time (although some of my cases extend back eight years) in which to record end results in this condition, inasmuch as five years, and more lately Dr. Maurice Richardson places seven years as the limit of safety as to possible recurrence. The pessimistic attitude of some surgeons that "once cancerous always cancerous," is not borne out by our more modern statistics.

My hospital and private practices record an experience of 92 cases of cancer of the breast, in which *x*-ray exposures followed operation. Of this number, I am unable to obtain the subsequent histories with the report of end results in 22 patients. This leaves 70 cases which can be reported after the elapse of the three-year limit, with the following results:

Dead	16
Living with recurrences	14
Dead of other causes than cancer	2
Living and apparently well	38

Of those reported living with recurrences five patients are still pursuing treatment with the rays; one patient who had kept up her treatments until a few weeks ago is practically moribund. Of those who are still living and apparently entirely well, two still keep up an occasional treatment. Patients having once undergone an operation for cancer are

*Paper read at a meeting of the Philadelphia Clinical Society, January 18, 1915.

probably rightly the most "scary" individuals in the world. The slightest thing will hasten them back to the surgeon or radiologist for an examination or treatment, and they are the most susceptible and gullible of any class of patients to the influence of the various cults and fads of medicine and surgery. The prosperity of the cancer quack and the so-called "plaster specialist" is confirmative proof of this.

These statistics may well bear further analysis, although all in all, the cases presented every variety of breast cancer, from the fairly benign adenocarcinoma to a fulminating medullary neoplasm. One case of so-called acute cancer occurred in the youngest patient of my series, a woman of 27, who from the time she noticed the primary growth, about the size of a small walnut, until her death with generalized metastatic growths of the abdominal viscera, only a period of four months elapsed. Two cases were in males, both advanced in life, one being 75, the other 66. One of these patients, the younger, died of a strangulated hernia; the other man is apparently well, although suffering from the infirmities of old age, as he is now near eighty.

In a review of all the cases operated upon at the St. Mary's Hospital, Rochester, Minn., up to 1913, E. S. Judd reports that of the 427 cases traced, 191 patients were living after three years, 19 were dead from other causes, 234 died from cancer, and in 27 cases there were recurrences at the present time. Forty-four per cent. of cases therefore have passed the three-year limit. Butlin in an analysis of 57 cases gives a ratio of over 50 per cent. of cures surviving without recurrences the three-year limit; Halsted's older statistics report over 50 per cent. of cures. In my series of 70 cases 53 per cent. have passed the three-year limit of safety. Even conceding the usually accepted dictum, that 20 per cent. of patients having safely passed the three-year period later have recurrences, the percentage of permanent cures of those treated at the present day is considerably larger than the statistics of the older surgeons—Banks, Estlander, König, Gress, and Bull—whose average of permanent cures is a trifle over 20 per cent. Probably the more favorable results secured in these later days is due to the fact that more radical operations are performed, and physicians by bitter experience have learned their lesson and are referring their patients to the surgeon earlier and before metastasis has occurred.

Conceding without question the universally adopted surgical axiom that all cases of breast cancer must be operated upon immediately, on even a presumptive diagnosis—even to discuss this is supererogatory—what is the rôle that the *x*-rays may be expected to play in the future therapeusis of the disease?

First, I believe the plan of a preliminary *x*-raying of the field previous to operation is now practically discarded, and yet the following abstract from an article on the subject by Hernon Johnson, appearing in the *Lancet* only last year, shows that our British confreres have not wholly abandoned the preoperative röntgenization of the field: "The commonly accepted dogma that operation should always take place immediately on the diagnosis of cancer ought to be subjected to fresh examination in the light of present knowledge. Surgical interference always involves risk of disseminating malignant cells. If all the cells of a cancerous growth are in a depressed state at the time of operation, there will always be less chance of establishing themselves at a distance in the face of normal opposition of invaded tissues. A very moderate amount of radiation is capable of producing a temporary depression in cancerous elements, three weeks' preoperative treatment being sufficient for the purpose. When pain and ulceration are present preoperation raying should be insisted on. The patient can in a few weeks be placed in a much better state to withstand operation."

The universal teaching, at least on this side of the Atlantic, is so opposed to these views—and probably rightly—that it is difficult to incline our views to delaying an urgent operation, in which procrastination means just so much further inroads of the disease, until, as Johnson puts it, temporary depression of the cancerous elements is produced.

Following operation how soon is it justifiable to place the patient under routine *x*-ray treatment? On the hypothesis—and it has not been disproved—that at operation some of the surrounding tissues have by traumatism been invaded by cancer cells, it would seem highly important to use the rays early and in large doses. If, as Leaf says in his admirable monograph on diseases of the breast, "recurrences always arise from cancer cells left behind at the time of operation," then to avoid further trouble it is essential to annihilate these cells of low vitality before they become potent for future mischief.

Patients recover usually sufficiently early from the shock of operation to permit *x*-ray treatment within a week. It is not the province of this paper to discuss the technical questions involved in the treatment. Sufficient to say that the breast is treated by the cross-fire method from four or five different angles; the axilla, the back, the supraclavicular area, and the opposite breast all being roentgenized. And on the basis of Handley's permeation theory in dissemination of cancer cells, I always routinely expose the epigastric angle to the full effects of the rays, hoping—very frequently, I admit, vainly—that abdominal visceral metastasis may be averted. A fairly hard tube is used, the rays are filtered through aluminum or leather and pushed to the limit of dermic toleration. This, the enthusiasts of *x*-ray dosology, to the contrary, can not always be accurately gauged, personal idiosyncrasy to the *x*-rays being somewhat of a factor, but careful supervision and watching will usually avert any serious consequence arising from a complicating dermatitis. Pfahler points out the danger of exposing the thyroid to the rays, producing thereby an artificial myxedema. He uses thyroid extract as a routine drug while the patient is under *x*-ray treatment. I have never encountered any thyroid complication of this nature in my cases, although it is well to bear the condition in mind. The theory that the loss of weight may be due to an athyrea is most probably erroneous, being due, in my judgment, to the inroads of the disease itself.

It is extremely difficult when to advise patients that treatments should be discontinued, as we never know when they are safely "out of the woods." In confirmation of this, Mayo's case of recurrence twelve years, Ransohoff's case of recurrence twenty years, and Matas' case twenty-five years after operation, may be cited. In a case uncomplicated by recurrences in which radical operation has been performed, I give routine treatments, using the cross-fire method up to the erythema dose for the first year, gradually diminishing the frequency of treatments in the second year to one every four or six weeks, and in the third year giving a prophy-

lactic raying of the breast and all contiguous structures once every two months. There is not much difficulty in persuading a patient who realizes the danger of her condition—and she should not be deceived or the seriousness of the disease minimized, as so frequently it is—such a patient is usually conscientious and persistent in following out her treatments.

When we come to a consideration of recurrences, we are dealing with a different and vastly more difficult problem. A nodula or lump appearing anywhere or at any time after the extirpation of the breast for cancer is a cause for alarm and calls for immediate and drastic action. Here surgery offers but little hope, the *x*-ray hardly much more. Either may for a time avert the fatal outcome, but at best the prospects are forebodyingly gloomy. True, occasionally—and this is indeed rare—we seem to be the victors over the cancerous onslaught, but at best it is but a temporary lull; the cancer army repulsed at one point finds a foothold somewhere else and treacherously invading numerous lymphatic paths—and to continue the military simile (it is the fashion these days)—lives on the country as it advances, and ultimately the invaded territory is entirely in the hands of the enemy.

Actual curing of a recurrent carcinoma is one of the anomalies of medicine, yet Pierce Gould reports such a case. in which despite repeated metastasis, the patient lived on for many years and finally died of some other disease. Autopsy disclosed that in the secondary nodules natural repair by fibrosis had occurred.

However, in a certain percentage of cases—alas, entirely too small—it may be possible for a time at least to avert the inevitable. Under the *x*-rays it is surprising how frequently these secondary nodules will melt down and to all appearances disappear; ulcerations granulate and apparently further carcinomatous inroads checked. A case exemplifying this is herewith reported:

Mrs. H. S.; æt. 45; widow; operated upon in the early part of 1908 by Dr. Louis Steinbach for a scirrhous carcinoma of the left breast; in August of the same year and without any visible or subjective evidence of the disease, she was referred for *x*-ray treatment and continued treatments faithfully until January, 1909; in May 1909, she came back for treatment of a lump about the size of a marble under the left axilla; in three weeks, during which time seven treatments were given, this had entirely disappeared. Three months later a lump which rapidly grew to the size of a small pigeon's egg appeared in the left axilla, somewhat posterior to the first nodule; this fairly melted down after three exposures to the *x*-rays; in June of the following year a series of eight or nine reddened bead-like nodules made their appearance along the line of the operative incision, at the lowermost point of which was an ulcerated area as large as a silver half dollar. This recurrence was extremely stubborn and required three months of persistent raying to cause effectual disappearance. Until this time, two years after the operation and notwithstanding her recurrences, she had actually gained eighteen pounds in weight. From this time on until her death in February, 1914. six years after her operation, she was treated for and had disappearance of nodules, twice in the left axilla, once in the right axilla, and again at the posterior angle of the left scapula where a growth nearly as large as a hen's egg disappeared after vigorous raying. Ultimately supraclavicular nodules appeared and despite the fact that treatment was pushed even to the extent of producing a decided skin reaction, no effect was apparent in the growths. And this has been my experience in every other case where secondary enlargement of the cervical lymph glands was present. These have invariably proved extremely resistant to treatment and I cannot recall any case in my series where supraclavicular involvement was present previous to operation where the patient has survived past the three year limit.

The patient died as a result of metastatic growths of the liver, although for a period of six months previous to her death, she was bedridden as a result of a spontaneous fracture of the femur, due no doubt to osseous involvement, and in which union had never occurred.

Another complication which it is seemingly impossible to mitigate by the Roentgen rays—and for that matter by any other method at present known—is the secondary edema of the arm. This is without doubt one of the most distressing complications of the disease, the arm in some cases swelling to three or four times its natural size, the weight and ensuing pain of the affected limb being unusually severe and distressing. For the relief of this condition, shoulder amputation has been advised, Rodman reporting a case in which temporary amelioration was secured by an interscapulothoracic amputation. Leaf has suggested resection of some of the branches of the brachial plexus for the relief of this so-called brawny arm, but I am unaware of any case in which it has been attempted.

I have had experience in but one case of sarcoma of the breast, and here metastatic involvment was so far advanced that *x*-ray treatment was abandoned after a few weeks, the patient living only eight weeks after operation. Rodman in his book on Diseases of the Breast (1908), writes of the encouraging results he has secured in the treatment of sarcoma by means of the *x*-ray, although he is pessimistic as to the value of the rays in mammary carcinoma, claiming that in certain cases the *x*-rays instead of checking seem to hasten the spread of the disease. I am unacquainted with Dr. Rodman's present attitude as to the status of the Roentgen rays.*

One striking result, I think, has been the experience of nearly all radiologists in the treatment of this condition, viz., the marked relief of pain which has so often resulted from *x*-ray treatment. This is undeniably true, the analgesia being more than psychic, as repeated reports of other observers attest. Handley in Choyce's "System of Surgery" speaks of this effect of the *x*-rays and cites a case in his own practice, where most pronounced relief was afforded by *x*-ray exposures, although previously the patient was most skeptical of its value.

Occasionally patients are referred for *x*-ray treatment in whom on account of advanced age or widespread disease operation is deemed inadvisable. Here we can hope for but little, except possibly alleviation of pain, or probably for a short time to delay the inevitable. And yet, I recall one case referred me by Dr. Jesse Arnold in a woman of 83 with an ulcerating scirrhus carcinoma of the breast in whom most striking improvement was induced by *x*-ray treatment. The ulceration closed over with scar tissue, the neoplasm diminished in size, and the patient lived in a fair degree of comfort for nearly three years, finally succumbing to pulmonary metastasis.

In his "Clinics" for October, 1914, Dr. John B. Murphy states the following in regard to the em-

*In an article by Dr. Rodman appearing in the issue of the *Journal of the American Medical Association* of February 27, 1915, there is a complete reversal of his earlier teachings as to the use of the *x*-ray in breast cancer. Since 1909 he has used it as a routine measure in all postoperative cases with marked success, and occasionally has achieved a surprisingly brilliant result in an apparently advanced case.

ployment of the *x*-ray in carcinoma of the breast: "We advise it, we order it, and we believe it does some good. Its retarding action in the development of a carcinoma is due we believe to the fact that it is capable of producing cicatrization or connective tissue formation around the malignant cells to the extent of strangulating them and on the malignant cells which have escaped from the primary focus into the neighboring tissues we believe it has some effect."

In the absence of any specific remedy at the present time for the cure of cancer, the status of present day treatment for carcinoma of the breast resolves itself, first and foremost, into early and wide removal of the diseased organ and all secondarily involved tissues, followed by thorough, persistent and continuous *x*-ray exposures over the site of operation and all contiguous areas.

1318 Locust Street.

Medicolegal Notes.

Malpractice—Choice of Alternative Methods—Proof of Negligence. — In an action for malpractice in the treatment of a simple fracture of the tibia, it appeared that, when the accident occurred, on January 4, 1910, there was no outward evidence that the tibia was in fact broken; the skin and flesh being unbroken and the leg apparently in normal alignment. The defendant was called shortly thereafter to treat the injury and upon examination discovered that the tibia was broken about four inches above the ankle. He set the broken bone and placed the leg in splints, it being necessary to place the plaintiff under an anesthetic in so doing. He then discussed with the plaintiff and his wife the various methods of treating fractures of this nature, particularly as to reuniting and holding the broken ends of the bone in place while healing. The plaintiff advised that the broken bone be re-united by the Lane method, consisting of opening the flesh and inserting and attaching to the broken portions of the bone a plate so as to hold them rigidly in apposition and alignment. The defendant advised this method of treatment in preference to other methods by which the bone is held in place by outward appliances without cutting the flesh, expressing the opinion that quicker and better results would follow. This method of treatment being consented to by the plaintiff and his wife, they relying upon the defendant's advice, upon the following day the plaintiff was taken to the hospital, where the operation and the insertion of the plate securing the broken portions of the bone in place was performed and the leg placed in a cast. The plaintiff remained at the hospital six days. The evidence did not furnish any information as to what occurred at the hospital other than that the operation was performed. No details were shown throwing any light upon the manner of performance of the operation, nor as to the care or want of care there exercised relative to possible infection of the injured parts. The plaintiff was then taken home, where the defendant cut a hole in the cast so as to render the flesh wound acessible for treatment, and it was then first discovered that the injured parts had become seriously infected. The broken parts of the bone thereafter grew together without resetting, so that, at the time of the trial, they were in good alignment and there was no shortening of the leg. In May, 1910, the plate was removed by the plaintiff, and because of the infection, which still persisted, and with a view of overcoming it, the plaintiff operated upon the leg again in August, 1910, and in January, 1911, otherwise treating it at intervals since the injury was received. The defendant, then being dissatisfied with the plaintiff's treatment, placed himself in the hands of another surgeon. Dr. Gardner, who in treating the leg with the view of overcoming the infection operated upon it in June and October, 1911. None of these operations by the defendant and Dr. Gardner involved the resetting of the broken bone; the first setting of it being followed by practically perfect results so far as alignment and maintaining the normal length of the limb were concerned. At the time of the trial the leg had practically regained its normal condition, except that it was not fully recovered as to its strength. The plaintiff was able to resume his usual work during only a portion of the time during the two years while being treated by the defendant and Dr. Gardner. The evidence showed that the only serious result to the plaintiff, aside from the suffering and loss which would necessarily, in any event, flow from such an accident, was the infection.

The defendant's theory was that the plaintiff was negligent in making use of the Lane method, which required the opening of the flesh to the bone in order to attach the plate thereto, and that he was thereafter negligent in using unsterilized water to cleanse the injured parts. The only evidence in support of the contention that the defendant was negligent in using the Lane method was furnished by Dr. Gardner, and of that, in the court's opinion, the most that could be said was that this method did not have, at that time, the unanimous approval of the medical professor. However, according to the only evidence presented in the plaintiff's behalf, that method did have the approval of a respectable minority of the medical profession, who recognized it as a proper method of treatment. This, the court thought, was enough to absolve the defendant from negligence so far as his mere use of that method was concerned; there being no showing that he exercised other than his best judgment in choosing that method. In Sawdey v. Spokane Falls & N. Ry. Co., 30 Wash. 349, the Washington court recognized the rule that if there be more than one recognized method applicable to a particular case, the attending physician is not liable for an honest mistake of judgment in his selection of the method of treatment.

There was no evidence but that every precaution known to medical science was exercised at the hospital looking to the prevention of infection. The only evidence of negligence was the bad result; the mere fact that the infection occurred. In Peterson v. Wells, 41 Wash., 693, 696, the court recognized the rule that a mere bad result is not of itself ordinarily sufficient to render an attending physician liable for negligence; that is, it is not ordinarily proof of the physician's negligence. Judgment for the defendant on a directed verdict was affirmed.—Lorenz v. Booth, Washington Supreme Court, 147 Pac. 31.

Malpractice—Excessive Damages—Care Required.— In an action against a surgeon for malpractice in treating the plaintiff for a broken and dislocated wrist, the jury were instructed that in estimating the plaintiff's damage, if any, they should consider the character and extent of her injury, whether it was permanent, the pain of body and anguish of mind she had suffered, if any, and would suffer in the future on account of the injury, and the impairment of her earning capacity, if any, etc., and assess her damages at such sum as would reasonably compensate her therefor, not to exceed the sums prayed for in the petition. It was held that this instruction was erroneous, as charging the physician with liability for all the results of the original accident in which the wrist was injured, as well as the necessary results of unskillful treatment. A broken arm is itself a serious injury, regardless of the way in which it is treated by the attending surgeon, and the attending surgeon cannot be held liable for all the damages growing out of the injury. He is not responsible for the original injury and its usual and natural consequences with proper treatment.

It was also held error to instruct that the care and skill a surgeon should use in his practice should be proportionate to the character of the injury he treats. It could not be said that his skill should increase in proportion to the severity of the injury. One's skill is a matter of slow growth and cannot be increased on short notice.—Fowler v. Burris, (Mo.) 171 S. W. 620.

Disease from Unsterilized Instruments — Liability.— In an action for negligence against a dentist the evidence tended to show that a gold crown was fitted for the plaintiff by an employee of the defendant; that in fitting the crown an instrument was used which cut the plaintiff's gum so that it bled, and about three weeks afterwards sores appeared in her mouth, one of them being at the point where the gum was cut. There was also evidence that she was then suffering from syphilis, from which she had hitherto been free. The jury found that the plaintiff was infected with syphilis through the negligence of some person employed by the defendant, whose duty it was to clean and sterilize the instruments used, and this was confirmed on appeal.—Drakes v. Tulloch, Massachusetts Supreme Court, 107 N. E. 916.

THE MENACE OF CANCER.

IN the current issue of the MEDICAL RECORD all of the original communications deal with cancer in one or more of its various aspects. This is in answer to the request of Dr. Wainwright of the Commission on Cancer of the Medical Society of the State of Pennsylvania, who has asked each of the medical journals of the country to devote its July issue, or, if a weekly, its first issue in July, to this subject, with the view of bringing to the general practitioner a full realization of the menace of cancer to mankind. We comply with this request gladly for, though we doubt very much whether cancer is increasing as rapidly as some alarmists would have us believe, it is nevertheless far too prevalent and every physician should realize that upon him rests the duty of doing what he can to stay the progress of the scourge. How this can best be done is a matter for study and deliberation, for the way is not clear and the guides themselves are far from agreed as to the proper course.

The profession is almost unanimous in the belief that, with few exceptions, once the malignant nature of a neoplasm is established it is the duty of the surgeon to remove it at the earliest possible moment and to extirpate it root and branch. But what then? Some enthusiastic surgeons believe that if the tumor is removed early enough the disease will be cured, but to make sure of this desirable result they insist upon operation at such an early period that the growth is really in the "precancerous" stage; that is to say, it is not yet malignant, and we may add no one can be sure that it ever will become malignant. When the tumor is a declared cancer no one dare affirm that it will not return, either *in situ* or in some more or less remote part, no matter how radical the operation for its removal may have been. For the extremist, therefore, who is often the most logical, the campaign against cancer is really one against all neoplasms—indeed, this is acknowledged by many, and only a few years ago a distinguished surgeon advised the extirpation of every pigmented mole and wart on the body, lest at some future time it might undergo malignant transformation. This would be as impractical—and as logical—as the excision of the appendix in the infant—a mutilation that has more than once been seriously advocated. The surgical treatment of cancer is therefore a failure—and we say this advisedly, knowing well that it is as yet the best treatment we have and that in a fair and possibly increasing proportion of cases the patient after operation rounds out his or her term of life without a return of any of the visible marks of the disease.

Surgical treatment nevertheless does not afford an absolute cure, and herein lies the weakness of the contention that cancer in its early stages, or at any stage, is a purely local disease. The argument for early operation is based upon this theory, but the result of early operation in many cases seems to disprove it. On the other hand, the theory of an infectious origin and the one which looks upon a malignant neoplasm as the local expression of a vice of metabolism are equally uncertain—at least the arguments in support of them are no more convincing. In fact, cancer is still, what it has always been, a mystery. It is impossible, however, to believe that it will always remain so. Many of the best minds in the profession are occupied solely with this problem and it is inconceivable that none of them will ever discover the secret of malignancy and the cause and pathogenesis of malignant disease. Until that is done, however, all attempts at a cure will be but groping in the dark. Such being the case the condemnation of every therapeutic effort other than surgical is itself to be condemned. Cures as absolute as any secured by operative removal have repeatedly followed other modes of treatment — chemotherapeutic, orrhotherapeutic, radiotherapeutic, and dietetic. It is no argument against the validity of such cures to say that they were merely examples of spontaneous recession of the disease, such as undoubtedly occurs. If a spontaneous cure of cancer occurs so frequently, as we must admit it does if we designate as such all non-operative recoveries, then surely there is hope of finding the reason for such a favorable change and making it the basis for successful therapy. We have intimated that no absolute cure for cancer will be found until the nature and origin of the disease are known, but it is very possible that the true cause may be revealed as a consequence of a stumbling upon a successful method of treatment. For this reason we believe it is wrong to oppose every therapeutic suggestion that does not fit in with the theories of the moment. Many theories, both therapeutic and pathogenic, in regard to cancer are of course wildly improbable, yet there is none so fantastic that it may not contain a suggestion which some other clearer visioned and more logical mind may seize upon and develop into a tenable and fruitful hypothesis.

VON PROWAZEK AND TYPHUS FEVER.

A TRUE spirit of internationalism characterizes the unselfish devotion of medical men in the present war. No sacrifices recently recorded have been more heroic than those of Donnelly and Cooke of New York, who succumbed to typhus in the overcrowded lazarettos of Serbia. Their death and the death of others who fought the invisible foe represent one of the most pathetic incidents of the great world tragedy.

A peculiar element of sadness pervades the obituary of Stanislaus von Prowazek, the director of the Protozoa Laboratory of the Institute for Marine and Tropical Diseases at Hamburg. His work upon the pathogenic rôle of the chlamydozoa had already placed him in the front rank of protozoologists, when two years ago he turned his attention to the study of typhus fever in the infected camps of the Balkan peninsula. In December, 1914, he was fighting this disease among the Russian prisoners in Cottbus, and on Feb. 17 he became a victim. Just three months later his studies in the etiology of typhus appear in the *Beiträge zur Klinik der Infektionskrankheiten und zur Immunitätsforschung*, Vol. IV, No. 1. A brief review of his observations, although they have recorded nothing that is absolutely new, may not be amiss.

Careful examination of the blood of typhus patients revealed the presence neither of protozoa nor of bacteria that could be regarded as bearing an etiological relationship to the disease. In one case in Hamburg small bacilli were observed in the polynuclear leucocytes, and in a few of the cases in Belgrade the so-called "Ricketts-Wilder bodies," the significance of which is still obscure. Stained blood smears showed the presence of round or whetstone shaped granules in the polynuclear leucocytes. The results of cultural experiments were negative, possibly owing to certain difficulties that surrounded the prosecution of this work.

Careful studies on the pathological anatomy of the disease were carried out in Serbia. Particularly characteristic were regarded the capillary changes in the skin, consisting chiefly in a hyaline degeneration and necrosis of the inner coats; inflammatory foci in the brain; the changes in the polynuclear leucocytes, and necrosis and caryorrhexis of the myelocytes and polynuclears of the bone marrow.

CONCERNING RHEUMATISM AND GOUT.

Of course, it is a fact that the term rheumatism is ambiguous, and to a large extent misleading. It is not really known exactly what rheumatism is. In the *Medical Press and Circular* of June 2, 1915, the subject is dealt with editorially in an interesting manner. It is pointed out that to define rheumatism correctly is about as difficult as to define truth. The definition of rheumatism must take a negative form, or is an uninforming negative. The realization of what rheumatism is not is beginning to impress itself upon the medical profession, and we can only hope to arrive at an accurate comprehension of the matter by a process of gradual exclusion, that is, if we ever do arrive at this goal.

According to this writer rheumatism has nothing to do with acute rheumatism or rheumatic fever. It has nothing to do with what the French call "arthritisme," a term which by a topsy-turvy process is used to describe all or any of the manifestations of rheumatism save only the arthritic, which are specifically excluded. Rheumatism has nothing to do whatever with uric acid, a senseless bogy, our contemporary says, badly designed by sad and silly herbivora to frighten the active and careless carnivora. Rheumatism has nothing to do with chorea, tonsillitis, subcutanous nodules, or erythema nodosum, all of which are said to have a real but hitherto unexplained relationship to acute rheumatism. It may be that the only connection between them is the sinister power common to them all, of giving rise to endocarditis, a relationship which is not real, but apparent only.

The entire editorial is a trenchant criticism of the hopeless muddle into which the true meaning and the terminology of the condition or conditions known as rheumatism has been brought. Sydenham is quoted as almost the sole authority on gout, and the writer of the editorial avers that the real kernel of Sydenham's classical and immortal description has been missed. Sydenham says that "great eaters are liable to gout, and of these the costive more especially," while in a previous part of his treatise he had declared that gout was due to "a vice of metabolism." The "costive" points unmistakably to the seat of the vice of metabolism, which is rather a vice of excretion than of metabolism. Intestinal stasis, bringing about alimentary toxemia and absorption of chemical poisons and bacteria into the circulation, may be the cause of gout and rheumatism both, taking these terms in their generally accepted meaning. The author concludes that after Sydenham, the only other authoritative writer on gout is Arbuthnot Lane. That the latter did not realize that he was more than half solving the problem detracts nothing from the value of his contribution. Some day there will arise a third writer who will still further clarify this jelly, and this he will do by means of an internal secretion.

There is a good deal of valuable suggestion in this prophecy. If intestinal stasis be long continued it is reasonable to suppose that alimentary toxemia will supervene; toxins may then be absorbed into the blood stream from the colon, and this may be the predominant factor in the causation of gout and of some phases of that condition denominated rheumatism. The day may dawn when the advocates of the intestinal stasis theory will be regarded in the light of true prophets—or their views may be forgotten or remembered only as one of the curiosities or absurdities of a past age.

CANCER EXTRACTS IN THE TREATMENT OF CANCER.

The use of cancer autolysates in the treatment of cancer was suggested simultaneously in 1902 by von Leyden and Blumenthal and by Jensen. The method has been employed with numerous variations by many other investigators, apparently with little success. Blumenthal, who still clings to this conception as one that promises definite therapeutic results, believes that cancer extracts contain antibodies or antiferments. Lewin, Erhard, Bertrand, and others who have applied Blumenthal's theory have succeeded in eradicating rat sarcomata and mouse carcinomata, but in the case of cancerous growths in human beings they have succeeded only in improving the general condition and in checking the growth of the tumor.

In 1913 Stammler, however, reported that with the intravenous injection of cancer extracts he had

succeeded in completely eradicating a secondary vaginal growth that had developed after the extirpation of a uterine carcinoma. Another line of investigation has consisted in effort to produce active immunization against cancer. The most fruitful results of this mode of treatment have been those reported by Fichera of Rome, who used autolysates of embryonal tissues, and Loeb and Fleisher of St. Louis, who injected intravenously such substances as casein and nucleoprotein.

Lunckenbein (*Beiträge zur Klinik der Infektionskrankheiten und zur Immunitätzforschung*, Vol. III, No. 3), in reviewing this entire field, finds that both with the use of specific tumor extracts and with the use of definite but non-specific protein substances, striking results have been obtained in arresting the development of malignant growths. He has evolved a method of treatment which he bases upon the following hypothesis: The substances that arouse the body to produce protective ferments reside in the nucleus of the cancer cells. As long as the nucleus is surrounded by the cell cytoplasm, the reactive power of the body is not stimulated. By injecting nuclear proteins into the circulation one may excite the production of the suitable protective ferments. These proteins are obtained from either sarcomata or carcinomata; in either instance they are said to be effective against both types of neoplasm. The mode of preparation is not explained. The therapeutic results so far obtained are said to be more favorable in sarcoma than in carcinoma.

Clean Dermatology

Skin affections generally are not easy to treat successfully. The difficulty in dermatology is to obtain asepsis, and thus the crux of the problem is clean dermatology, for in skin complaints antiseptic measures cannot be applied with the same hope of success as in surgery. Dr. Alfred Eddowes in the *Medical Press and Circular* of June 2, points out the obstacles in the way of curing such skin diseases as for instance ringworm, red eczema, and sycosis, for mild or strong remedies may fail unless handled with skill. In corroboration of this statement a case of impetigo spread all over the face to which had been applied a too weak lotion for the initial lesion. The application of a lotion not sufficiently strong allows the disease to spread, but, on the other hand, if the applications are too strong the skin becomes inflamed. The good results obtained from cleanliness in the treatment of skin affections was known, in a measure, to dermatologists long before Lister's time, but it remained for Lister to explain and give them their guiding principle. Eddowes proves his contention by some illustrative cases. He saw several cases of red eczema on scalps of children in a skin clinic and was asked if he could suggest any treatment. He recommended that they be cleaned once with spirits and then covered up with paste for a whole week. This treatment acted like magic, and it was the cleaning that did it. Other cases are referred to, and the axiom is laid down that the secret of success was the principle: Clean antiseptically, then soothe with dressings mild but antiseptic enough to hold on to the ground gained.

News of the Week.

New York City Death Rate.—During the week ending June 19 there was a marked increase in deaths from children's diseases in this city as compared with the corresponding week in 1914. Measles, scarlet fever, diphtheria, and whooping cough claimed eighty-two during the week, as against forty-eight in the corresponding week last year. This was part of a general mortality increase of 170 deaths, the total being 1392, an increase of 1.09 points per 1000 of population. Children under five years showed a death increase of eighty-five and old people over sixty-five an increase of forty-three. The death rate for the first twenty-five weeks of 1915 was 14.32 per 1000 of the population as against the rate of 14.91 in the corresponding period of 1914, a decrease of 0.59 of a point.

Infant Death Rate in New York State.—The death rate of infants less than one year old, in New York State, outside of New York City, for May was sixteen points less than a year ago, according to a statement recently issued by the State Health Department. The rate in May, 1914, was 102 a 1000, while this year it was eighty-six. In New York City the rate last month over the same month a year ago increased nine points to 107 a 1000. In the State, outside of New York City, there were 300 more births in May, 1915, than in the same month last year.

Columbia Students to Aid Serbia.—Twenty-four Columbia University medical students who sailed for Serbia last Saturday for relief work were the guests of honor at a reception given one evening last week at the Hotel Majestic by the Daughters of Oneida. They sailed on the Greek steamer *Themistocles*, taking with them twenty-five motor ambulances and a full equipment for each.

The Second Harvard Hospital Unit, under the command of Dr. E. H. Nichols, assistant professor of surgery at Harvard, sailed on the Holland-America liner *Noordam* last Saturday. The unit will be attached to the Royal Army Medical Corps.

Janeway Lectureship at Mt. Sinai Hospital.—Through the generosity of an anonymous donor, a lectureship has been established at the Mount Sinai Hospital named after the late Dr. Edward G. Janeway, who was for many years associated with the medical staff. The foundation has been created for the purpose of inviting important investigators to present the results of their work to the staff of the hospital.

Medical Inspection of Schools in Florida.—The Florida Legislature has just passed an act which provides for thorough examination of all school children of the State, including the rural schools, under the direction of the State Board of Health. The bill also provides for the sanitary survey of all school buildings and their surroundings. This bill was drawn up by Dr. Oliver J. Miller, city health officer of Sanford, and was introduced in the House of Representatives by Hon. Forest Lake of the same city.

New Research Laboratory.—Plans are being prepared for the construction of a seven-story fireproof laboratory on the site of the present power house on the grounds of the Rockefeller Institute for Medical Research. The building will be 150 by 60 ft. and will be equipped for research work. Adjoining the laboratory a house for keeping animals for vivisection and observation purposes will be built.

Pan-American Medical Congress.—At the seventh congress, held in San Francisco on June 17-21, 1915, the following were elected to the National Executive Committee. *President*, Dr. C. A. L. Reed of Cincinnati; *Vice-President*, Dr. Henry L. E. Johnston of Washington; *Secretary General*, Dr. Ramon Guiteras of New York. After the adjournment of the American Medical Association the official delegates to the United States went as guests of the United States Government on a sight-seeing trip to Santa Barbara, Los Angeles, San Diego (Panama-California Exposition), the Grand Cañon of the Colorado, and the Yosemite Valley. The trip started on June 26 and returned to San Francisco on July 4. It was under the direction and management of Dr. H. L. E. Johnson of Washington, D. C., representing the United States Department of State and the President of the International Executive Commission of the Congress.

The Federal Board of Medical Examiners.—At the meeting on Thursday, June 24, of the House of Delegates of the American Medical Association, Dr. Rodman presented the scheme of federal examination and licensure, which he had outlined in his presidential address, and asked the House to give its sanction to the plan. After a discussion the delegates refused their approval, but voted to refer the whole matter to the Council in Medical Education for investigation and report.

The "School Health News."—In his annual report to the Mayor, Health Commissioner Goldwater of New York announces that, in collaboration with the Department of Education, a publication entitled *School Health News*, designed in part for the instruction of school teachers in matters of hygiene, and in part to stimulate co-operation between the school doctors and nurses on the one hand, and school principles and teachers on the other, has been placed in the field under the editorship of the Bureau of Public Health Education.

Vitality Tests for Teachers.—Dr. C. Ward Crampton, director of physical training in the Board of Education, has undertaken an investigation to determine whether the New York public school teachers are overworked. He is applying the blood-pressure vitality test to about 200 teachers in the elementary and high schools of the city and at the close of the summer vacation will apply the tests again and note whether the difference is such as to indicate that the working year has been a severe strain.

Consumptives Advised to Stay at Home.—The National Association for the Study and Prevention of Tuberculosis has issued a bulletin advising that only those consumptives who have at least $1,000 to spend should attempt to make a new home in the West. The bulletin says that tuberculosis can be cured anywhere, and it is far better for a patient of moderate means, such as the average workingman, to go to a sanatorium near home, than to go West and live in perhaps a more favorable climate, but without proper food or medical care. Furthermore, although there may be plenty to do in the West and Southwest for ablebodied men, the consumptive will find the greatest difficulty in getting work, and no one should go West therefore in the hope of getting a job.

Dr. Donald Campbell of Butte, Mont.—In our announcement of the election of officers of the American Medical Association last week, the telegraph made us give the residence of Dr. Donald Campbell, Third Vice-President, as Montreal; it should have been Montana.

Dr. Henry M. Pollock, superintendent of the Norwich, Conn., Hospital for the Insane at Brewster's Neck, has accepted the invitation of the trustees of the Massachusetts Homeopathic Hospital of Boston to become the superintendent of that institution. He will not assume his new duties until February next as he wishes first to see the new inebriates farm in connection with the Norwich Hospital well established.

Dr. William B. Buck, superintendent of the Seibert Institute for Children, Philadelphia, has been appointed superintendent of the New York City Children's Hospital and Schools on Randall's Island. He succeeds Joseph D. Flick, head of the Staten Island Farm Colony of the Department of Charities, who was made temporary superintendent when Mrs. Mary C. Dunphy was dismissed after a service of more than twenty years.

Dr. Dora W. Faxon has been appointed second assistant physician at the Foxboro, Mass., State Hospital for the Insane to succeed Dr. George E. McPherson who has resigned to become connected with the psychopathic department of the Boston State Hospital. Dr. Faxon was formerly assistant physician at the Wrentham State School for the Feebleminded.

Dr. Richard H. Creel of the U. S. Public Health Service has accepted the appointment as chief health officer of Boston. The former three-headed health board has been abolished and Dr. Creel will be the sole responsible head of the department.

Dr. William J. MacNeal has been appointed director of the laboratories of the New York Post-Graduate School and Hospital to succeed Dr. Jonathan Wright, resigned.

Report of the Treasurer of the Committee of American Physicians for the Aid of the Belgian Profession.—Dr. F. F. Simpson, 7048 Jenkins Arcade Building, Pittsburgh, reports the following contributions received during the week ending June 26, 1915:

Dr. Emery R. Hayhurst, Columbus, Ohio	$5.00
Benton County Medical Society, Rogers, Ark	5.00
Receipts for the week ending June 26	$10.00
Previously reported receipts	7,447.00
Total receipts	$7,457.00

Medical Society Elections.—THE AMERICAN SOCIETY OF TROPICAL MEDICINE, at its annual meeting in San Francisco on June 15, elected the following officers: *President*, Dr. Milton J. Rosenau, Boston; *First Vice-president*, Dr. Bailey K. Ashford, San Juan; *Second Vice-President*, Dr. C. C. Bass, New Orleans; *Secretary*, Dr. John M. Swan, Rochester, N. Y.

THE CHICAGO MEDICAL SOCIETY at its annual meeting on June 15 elected the following officers: *President*, Dr. A. Augustus O'Neill; *Secretary*, Dr. Charles E. Humiston; *Councillors*, Drs. Charles H. Miller, C. C. O'Byrne, Douglas A. Payne, Fred. L. Glenn, and J. C. Krafft.

THE WASHINGTON ASSOCIATION FOR THE PREVENTION AND RELIEF OF TUBERCULOSIS, at its annual meeting in Seattle on June 14, elected the following officers: *President*, Dr. Christen Querli of Tacoma; *Vice-Presidents*, Drs. Wilson Johnston of Spokane and C. A. Smith of Seattle; *Secretary*, Prof. John Weinzirl of Seattle; *Treasurer*, Mr. J. V. A. Smith of Seattle.

THE WORCESTER DISTRICT (MASS.) MEDICAL SOCIETY, at its annual meeting held May 12, elected

the following officers: *President*, Dr. Ray W. Green; *Vice-President and Treasurer*, Dr. George O. Ward; *Secretary*, Dr. Ernest L. Hunt; *Orator*, Dr. John T. McGillicuddy; *Librarian*, Dr. George O. Lincoln.

THE WEST VIRGINIA MEDICAL ASSOCIATION, at its annual meeting in May, elected the following officers: *President*, Dr. A. P. Butt of Davis; *First Vice-President*, Dr. A. S. Bosworth of Elkins; *Second Vice-President*, Dr. G. C. Schoolfield of Charleston; *Third Vice-President*, Dr. S. P. Lawson of Logan; *Secretary*, Dr. J. Howard Anderson of Marytown; *Treasurer*, Dr. H. G. Nicholson of Charleston; *Editor*, Dr. S. L. Jepson of Wheeling. Wheeling was chosen as the 1916 meeting place.

Obituary Notes.—Dr. WILLIAM H. GREGG, for many years a prominent scientist in this State, died Monday at St. Cloud, Fla., where he went several months ago for his health. He was born in Elmira, N. Y., eighty-five years ago. He had been a practising physician in New York City and in Port Chester, N. Y., but several years ago he retired from active practice. Dr. Gregg was graduated from the College of Physicians and Surgeons of New York in 1857. He served as interne in Charity Hospital, Blackwell's Island, and then practised for a time in New York City. At the outbreak of the Civil War he became surgeon of the Sixty-ninth New York Regiment and subsequently hospital surgeon of the Eighth Brigade and senior inspecting surgeon. Dr. Gregg's scientific work was principally in chemistry, mineralogy, and ornithology.

Dr. MAURICE J. O'CONNOR of Williams, Ia., a graduate of the Northwestern University Medical School, Chicago, in 1903, and a member of the Maine Medical Association, died at St. Joseph's Hospital, Webster City, as the result of injuries sustained in an automobile accident on June 7, aged 38 years.

Dr. HENRY OSBORN HANAWALT of Kansas City, Mo., a graduate of the Medical College of Ohio, Cincinnati, in 1873, and until recently professor of neurology in the University of Kansas, School of Medicine, died at his home on June 5, aged 70 years.

Dr. HENRY JANES of Waterbury, Vt., a graduate of the College of Physicians and Surgeons, New York, in 1855, a surgeon in the United States Army during the Civil War, and a member of the American Medical Association and the Vermont State Medical Society, died at his home on June 11, aged 83 years.

Dr. FANUEIL DUNKIN WEISSE of this city died June 22 in his seventy-third year. He was born in Watertown, Mass., and was graduated from the Medical College of New York University in 1864, and a year later become Lecturer in Dermatology at the university. Dr. Weisse was a former Professor of Surgical Pathology at the New York College of Veterinary Surgeons and for many years was Professor of Anatomy, Surgical Pathology, and Oral Surgery at the New York College of Dentistry. In 1886 he published "Practical Human Anatomy," and was also the author of numerous contributions to medical literature.

Dr. W. C. COSLY of Slaughterville, Ky., died of apoplexy on June 15. He was a graduate of the Medical Department of the University of Tennessee in 1893.

Dr. JOHN FRAYNE, interne at the State Hospital at Scranton, Pa., died suddenly on June 17 at the age of 29 years.

Correspondence.

OUR LONDON LETTER

(From Our Regular Correspondent.)

GENERAL MEDICAL COUNCIL—SESSION FOR THE YEAR, JUNE 1 TO 4—ROYAL SOCIETY OF MEDICINE ON THE WAR—INSURANCE AND COST OF PRESCRIPTIONS—INFECTIOUS DISEASES, FATALITY AND PREVALENCE.

LONDON, June 11, 1915.

THE General Medical Council has held its annual session. A good deal of formal business was transacted, and various professional problems discussed, the whole proceedings having been laid down in the usual introduction, address of the president, Sir Donald MacAlister. The reports of the several committees were received and approved. The elections for the coming year were proceeded with, and the council being thus in order for work considered some cases of misdemeanor in a professional respect and pronounced judgment upon them, having heard evidence in public and deliberated *in camera*. Sentences of removal from the Dentists' Register and from the General Medical Register in cases in which the council found that the accused had been guilty of "infamous conduct in a professional respect" (the words of the act).

Reports from the several committees that had definite subjects submitted to them were received, and for the most part approved. Nominations of the Branch Councils for these committees were also received and acted upon.

The educational committee's report consisted of two distinct parts. As to one a communication had been received from National Board of Education dealing with proposals in regard to secondary schools. This was ordered to be appended to the report and the whole to be entered on the minutes as received and approved. In like manner the other part was treated in connection with a letter from the Pharmaceutical Society in reference to the alleged shortage of medical practitioners. This part of the report with the letter appended was approved to be entered.

For the public health committee the chairman made an oral report in regard to having requested the registrar to prepare certain statistics. This was approved.

For the examination committee the chairman submitted an account of the analysis of the annual tables compiled for the council, which was also ordered to be entered on the minutes.

Mr. James Rae attended for the National Insurance Commissioners to explain the mode of transfer of panel patients from one practitioner to another. He replied to questions put to him through the chair and received the thanks of the council for his assistance, as also did the commissioners.

Recommendations of examination committee respecting the Indian department, the certificates of Indian students and their registration when qualified, were also brought forward, adopted and forwarded to the India office.

The license of the Dublin Apothecaries' Hall gave rise to some discussion, but a motion was carried by twenty-nine to two that it was not such as to secure the requisite knowledge and skill for practising the profession.

A committee of the Royal Society of Medicine appointed to consider matters connected with the war, provided the police authorities with a list of hos-

pitals and other institutions which could receive patients, with a map showing the position of each. It also engaged to send surgeons with anesthetics on the request of the police to any point where they were needed. Sir Rickman Godlee is the chairman of this committee and Mr. J. Y. M. MacAlister, honorary secretary.

The committee has also been in communication with the war office concerning what surgical measures should be arranged for in anticipation that the threats of Zeppelin attacks on the east coast may possibly culminate in some attempts to fulfill them.

There has been a good deal of talk about the expense of carrying out the Insurance Act in different places. The cost of prescriptions has varied so much, accusations of extravagance in some cases have been so freely made, that it has been proposed for the High Courts to surcharge practitioners who may be reported by the panel committees of disregard of reasonable economy. The Medical Defence Union will challenge the right of the courts to interpose, but this step will perhaps lack support enough from the general body of members to justify legal proceedings. There seems no doubt that in some cases there has been extremely heavy cost and that perhaps more in London than in country areas.

It has been repeated in different directions that some men have deliberately set themselves to prescribe the most expensive articles in the hope of defeating the panel system. Their colleagues are their accusers. It is said even advertised proprietary preparations have been ordered for which no other purpose can be assumed. If this should be substantiated it would deserve the condemnation of the profession as much as, or more than, of the public. I hope investigation will prove that no medical man has been guilty of such conduct.

Enteric fever, according to the report of the Registrar-General, had the lowest recorded mortality in the two years, 1912 and 1913. In the latter it was at the rate of forty-one per million living. In 1912 it was forty-four. The loss of life, like the prevalence, was as irregularly distributed as usual, and the excessive mortality associated with urban conditions. Certain counties and boroughs experienced a mortality of 110 per million in the last three years and these localities are, for the most part, backward in sanitation. In contrast with them London was specially favored as to both prevalence and mortality. There has been a great increase of hospital treatment of late years and this must, without doubt, lessen the chances of infection on which so much depends. The isolation here, as everywhere, must limit the prevalence. In 1912 the deaths from typhoid were 48 per cent of the total; in the previous year the ratio was 50 per cent.

In the same report we find the mortality from scarlet fever was at the rate of fifty-seven per million living, at all ages, but 171 per million under the age of 15. The decline of the mortality from this disease for the last half century is remarkable. About 65 per cent of the deaths occurred in hospitals; in London the proportion was 94 per cent, but in rural districts only 40 per cent.

About half the deaths from croup and diphtheria are registered in public institutions. Of those in London about 80 per cent occur in the hospitals of the Metropolitan Asylums Board. It is therefore possible to compare the mortality with that of years before antitoxin came into use. Since 1890-3 the case fatality has fallen from 304 per 1000 admissions to sixty-five per 1000 in 1913. Not less than 97 per cent of the deaths were under the age of 15. Although the fatality from diphtheria was higher in northern districts the prevalence of the disease seems to have been at its lowest as indicated by notification. Cases of a milder type probably account for this, but bacterial investigation is necessary to clear up the question.

Progress of Medical Science.

Boston Medical and Surgical Journal

June 17, 1915.

1. An Anatomical and Mechanistic Conception of Disease, J. E. Goldthwait.
2. Syphilis and Lung Disease. A. F. Downing.
3. Rabies in China. A. C. Reed.
4. Tuberculous Infection as a Disease Entity. G. T. Palmer.
5. Program and Directions for the Mental Examination of Asocial, Psychopathic, and Doubtful Subjects. R. S. Hardwick.

1. An Anatomical and Mechanistic Conception of Disease.—J. E. Goldthwait distinguishes the two well-marked variations from the normal type of body structure as follows: In the splanchnoptotic or carnivorous type the figure is slender, the skin soft and delicate, the hair is abundant, the head is proportionately large, and the face and jaw are narrow. The palatal arch is high. The adenoid and tonsillar tissues are apt to be excessive. The torso is longer than the so-called normal and is also narrower. The increased length is chiefly in the lumbar region. The ribs are usually longer than is normal. The downward inclination of the lower ribs is very marked. The spine is smaller than normal and the lumbar vertebræ are more like the so-called normal dorsal vertebræ in shape. The stomach is long and tubular. Its attachments are less firm. The small intestine as a whole is much shorter than normal. In marked contrast to this type is the herbivorous type represented by the heavily built, broad-backed individual. From the purely medical point of view the recognition of these different types is important since the types apparently carry their own potential of disease. The tuberculous infection and the infections in general, the nervous diseases and acute mental disorders, the hyperglandular disturbances, the progressive anemias, the atrophic arthritis, many of the intestinal disorders, etc., naturally are associated with the slender type. The arteriosclerosis, hypertrophic arthritis, gout, diabetes (not the insipidus), chronic disease of the kidney, gallstones, the prostatic hypertrophy, the degenerative mental disorders, etc., are common to the heavy type. The suggestiveness of this in treatment must be obvious. The author presents a series of deductions of which the following are some of the more important: Symptoms should be interpreted in relation to that which is normal for the special type of anatomy of the patient. Abdominal conditions should be given proper anatomical and mechanistic consideration. With the presence of sugar in the urine it is not impossible that as well as improper food the pressure of the mobile, heavy organs upon the pancreas, or its blood vessels, may be distinctly causative of the symptom. In considering the blood diseases, especially the profound anemias, which cannot be explained in other ways, the position of the spleen or the effect which other organs may have upon its function should be considered. Many individuals belonging to the slender type which because of its low resistance has added so much to the mortality of infancy and childhood, are now being saved. With this type growth without proper guidance inevitably produces a still weaker physique, with drooped figure, narrow chest, etc. These acquired characteristics added to the congenital form accentuate

the congenital elements to such an extent that they are much more sure of being present in the following generation.

2. Syphilis and Lung Disease.—A. F. Downing states that in acquired syphilis there is a second or interstitial form as distinguished from the one with multiple gummata. In the former type, met with post mortem in old syphilitic subjects, the fibrous tissue is seen most commonly and abundantly at the hilus of the lung, whence it may extend as dense bands into the interior along the air tubes and blood vessels. It may be quite general and lead to extensive pulmonary fibrosis and shrinkage, or it may occur in scattered areas. The disease is usually unilateral and there are commonly also dense, firm adhesions in the pleural cavity. This interstitial hyperplasia displays no characteristics that serve to distinguish it from fibrosis due to tuberculosis, unless it be its tendency to be confined to but one lung, and to occupy the middle parts of the organ. It is this difficulty probably in distinguishing between the two that makes the autopsy records show so few cases of specific lung disease.

3. Atrophy and Syphilis of the Skin.—F. Wise reports a case which is said to constitute the second recorded instance of the coexistence of diffuse cutaneous atrophy and syphilis of the skin, that of Fordyce being the first. Aside from the fact that both disease processes existed at the same time and in the same integument in both patients, no parallelisms can be adduced from a comparison between the two cases. In Fordyce's patient the syphilis antedated the diffuse atrophy and may very well have been the cause of it. In the author's case the conditions were reversed, so that the question of a syphilitic etiology cannot be taken into consideration. In the author's case the advent of a syphilitic infection seemed to exert no appreciable changes upon the preexisting atrophic skin, nor did vigorous antiluetic medication affect the latter in any way. It has been pretty definitely established that atrophy of the skin, of the macular type, may follow as the result of a preexisting cutaneous syphilide. It is also probable that macular atrophy may appear in syphilitics without being preceded by syphilitic cutaneous lesions, as in Mibelli's case. The occurrence of diffuse cutaneous atrophy of syphilitic etiology and pathogenesis is recorded in but one instance. Much further study would be required to determine the question of cause and effect between the two conditions.

6. Diseases of the Esophagus.—W. Lerche concludes that all affections of the gullet have one main symptom in common, *i.e.* the disturbance of deglutition, hence the impossibility of making positive diagnosis without the aid of the esophagoscope. A local neurosis is present in every case of anatomical lesion of the gullet—at some time. The local neurosis is the "signal of distress of the gullet" and is a call for esophagoscopic examination. Where a disturbance of deglutition is present it is just as important to demonstrate the absence of a lesion as to demonstrate its presence.

8. Colloidal Gold Test.—A. I. Rubenstine and M. Schwartz find that Lange's colloidal gold test gives specific reactions in cerebrospinal syphilis, tabes, and paresis, as well as in infectious meningitis, while normal spinal fluids show negative reactions. There is no difference in reaction observed between the various forms of syphilitic infections. Lange's test should, whenever possible, be used as an adjunct in the diagnosis of cerebrospinal affections in conjunction with the Wassermann test, cytological examination, and protein estimation.

9. Horse Serum in Hemorrhagic Disease of the Newborn.—A. Hymanson notes that in this disease the coagulation time of the blood is somewhat delayed. As there is always a difficulty in obtaining human blood or fresh human blood serum, fresh horse serum, or rabbit serum serves the purpose almost as well. In the newly born infant, when the bleeding is not spurious, the horse serum should be administered early and repeatedly until bleeding ceases. The report of the injurious effect occasionally caused by the use of foreign serum is greatly exaggerated.

9. History of a Typhoid Carrier.—W. A. Sawyer details the later history of a typhoid carrier who, although frequent examinations of his feces gave negative results for four months after he had been treated with autogenous typhoid vaccine, nevertheless infected three persons when subsequently released from quarantine on parole. The total number of persons infected by this carrier is thirty, including five who died. In a further attempt to cure this carrier, the gallbladder and its duct were removed surgically, but the typhoid bacillus was found in the feces several times after the operation. Examination of the gallbladder showed that it was normal and that its contents were free from typhoid bacilli. After forty-one successive examinations of feces during a period of fourteen months, all with negative results, the typhoid bacillus was isolated from stomach contents containing bile. Certain typhoid carriers are unusually dangerous and must be controlled by quarantine or other adequate supervision.

12. **Prognosis of Auricular Fibrillation.**—H. E. B. Pardee states that the continuous irregularity of auricular fibrillation has been looked on as causing a poor prognosis. This is due to stopping treatment as soon as the patient recovers from an attack of acute cardiac failure. By continuing the digitalis in sufficient quantity to keep the heart slowed to about seventy beats per minute, there will not be a recurrence of the cardiac failure. Seven such cases are cited in which the patients have remained under treatment without cardiac symptoms for periods of from seven months to three years. Since these cases are all complicated by conditions of considerable gravity, and since they have performed such considerable physical exertion so long as their heart was maintained at a slow rate, it is concluded that the irregularity *per se* adds little or nothing to the gravity of the prognosis of the individual.

1. **Congenital Lesions of the Small Intestine.**—J. H. Evans states that several hypotheses have been put forward in explanation of atresiæ and stenoses of the small intestine: (1) Intrauterine peritonitis; (2) ulceration, ulcerative contraction; (3) pressure from tumors; (4) pressure from amniotic bands; (5) embolism or thrombosis of the superior mesenteric vessels; (6) inguinal hernia, volvulus, intussusception; (7) traction of the omphalomesenteric duct; (8) enlarged valvulæ conniventes, and (9) non-liquefaction and non-disappearance of the epithelium-occlusion and ingrowth of the mesenchyme. During the nineteenth century another hypothesis, in which fetal volvulus is considered to be the common etiological cause, appeared extensively in the literature of the subject. Of all the conditions which arise from the persistence of the omphalomesenteric duct or vascular bundle the most frequent is undoubtedly intestinal obstruction. This complication, which is one of the gravest, has long been known. Internal strangulation associated with a diverticular fistula has for its causation bands or loops. Intussusception of Meckel's diverticulum, when the diverticulum is fixed and patent at the umbilicus, is very rare. Nevertheless, even an instance of a retrograde diverticular intussusception—*i.e.* in which the distal end of the intestine became invaginated—has been placed on record. Also the diverticulum when free becomes inverted and, acting as a polypus, causes an intussusception, or the invagination of the intestine is produced in the proximity of a diverticulum without its walls being turned in. Volvulus of the diverticulum of Meckel belongs to the category of curious pathological and rare occurrences. There are only four cases in literature. Hernia of the diverticulum of Meckel may be found at birth; firstly, as the only content of the hernial sac—in this exceptional occurrence its interest is in connection with the enteroumbilical fistula which may arise therefrom; or, secondly, associated with other portions of the intestine, when there is an omphalocele, only observed after death or where life is impossible, and accordingly of no practical importance. Cysts which are of vitelline origin may be classified according to their situation: (1) Intramesenteric or retroperitoneal; (2) diverticular, (a) enterocyst of Gfeller, (b) enterocyst of Roth, and (c) enterocyst of free diverticulum: (3) umbilical, (a) retroparietal or properitoneal, (b) intraparietal or intramuscular, and (c) properietal or subcutaneous; (4) funicular, and (5) terminal.

1. **Ureteral Stone.**—J. H. Watson states that stone in the ureter is more prevalent than generally supposed. Stones may arise in the ureter but as a rule they form in the renal pelvis and then pass into the ureter. They are usually single, occasionally multiple and partly bilateral. The general effects of ureteral calculi may be set down as: (1) Those due to mechanical obstruction, (a) retention of urine behind the calculus, (b) interference with the function of the kidney of the same side, for example, hydronephrosis and pressure atrophy of the gland, (c) reflex effect on the other kidney may give rise to anuria; (2) effects due to infection: pyelitis, pyelonephritis, pyonephrosis; (3) secondary effects on the nervous system resulting from constant pain and irritation; (4) local effects on the ureter: mechanical—dilatation with or without hypertrophy and inflammatory—leading to changes in the wall, for example, ulceration, fibrosis, and, rarely abscess.

4. **Acute Gonorrhea Treated by Electrolysis.**—C. Russ describes this method as follows: The patient is made to retain urine for a few hours and the rate of discharge is visible on a disc of cotton retained within the prepuce. A Gram-stained smear is made of the discharge at the outset of the treatment. The patient is directed to pass about half of the urine he is retaining and keep the rest back. This preliminary urination washes the urethra from behind and is the only lavage employed. He then reclines on the couch and a platinized catheter is lubricated and passed gently down to the compressor urethræ. This catheter is quite smooth, has numerous perforations, and it is furnished with a stylet of platinum wire and a rubber collar which just enters the meatus. The author also uses rubber perforated catheters. A lint-covered pad lined by a flexible metallic core is wrung out in warm saline and applied to the perineum, scrotum, and root of the penis. A 2 per cent. solution of sodium iodide is then gently injected into the catheter. The rubber collar prevents its flowing away between the instrument and the urethra. The pad is connected to the negative, and the stylet (within the catheter) to the positive pole of the battery. A current of one to two milliamperes is passed for twenty-five minutes and the catheter is kept full of the solution from time to time by means of a syringe. The current being turned off, the catheter is withdrawn and placed in a glass of water. After the first few treatments the perforations in the catheter will be seen choked with masses of yellowish mucopus which are laden with gonococci, and these have been drawn from the urethra. On shaking the catheter in the water most of these masses become detached from the instrument and soon settle at the bottom of the vessel. The patient now passes the rest of the urine, and similar masses of mucopus will be seen in it. As the patient progresses this harvest diminishes, and when the discharge has ceased there is nothing visible in the perforations at the

end of such treatment. The author has applied this treatment every day to these cases of acute gonorrhea, and the signs of progress are: (1) The abolition of the scalding during urination; (2) the reduction and disappearance of the discharge. The amount of the discharge can be visibly measured by comparison of the patient's disc of wool from day to day, provided the number of hours' abstinence from urination is the same. When the discharge has ceased the battery is applied every other day, and after three to six more applications the urine is free from purulent threads. The treatment is painless and apparently produces no bad effects.

War and Sexual Diseases.—Touton delivered an address on this subject to a mixed audience. It was, of course, foreseen that in the present war venereal diseases would play a prominent rôle, and at an early period preparations were made for special central hospitals and transportation facilities. At Wiesbaden an old garrison hospital was made over into a central station for patients with skin and venereal diseases. There were thirty beds for soldiers with these affections. This service was a very small one compared with the large hospital at Mainz with its 500 beds for the same classes of affections. The latter was favorably situated for receiving overflow patients from the Wiesbaden station, which chiefly served as a model for small local hospitals. The author quotes an estimate that the equivalent of an entire army corps has thus far suffered from venereal disease alone, *i.e.* has been incapacitated thereby from service. These figures serve to shatter rudely the beliefs expressed by some optimists that the patriotic and idealistic emotions let loose by the war would lead to an unprecedented mortification of the flesh. The war, however, will not make German angels out of the German people. The author, alluding to the inevitable association of Mars and Venus, mentions the alleged appearance of epidemic syphilis at the siege of Naples in 1495. Whether or not such an epidemic really occurred no man knows. It is a somewhat academic question. What we do know is that many soldiers in this campaign became incapacitated from duty as a result of venereal disease, so that the latter was spread throughout Europe. Since that period siege and occupation have been the chief occasions for the contraction of syphilis by troops. Prolonged repression of the sex impulse such as results from life on the march and in the trenches appears to be satisfied at last only in association with cruelty. The author does not refer here to attacks on the respectable women of the conquered races. Even the prostitutes are assailed with fury and in total disregard of their physical condition. Preaching, enlightenment, the author does not recognize. It does no good to tell soldiers that continence is best for them. The author would ignore this teaching, however much he may believe in its truth. He would improve certain particular opportunities. The soldier invalided home is a source of danger to the civilian population, because being in forced idleness he is thrown in among women of all kinds. The young ladies idolize him, look upon him as half divine. Some among them who are neurasthenics and hystericals meet him in connection with voluntary convalescent nursing. Recently, as a result of a painful experience resulting from these associations, the young women personnel in a "convalescent home for the slightly wounded" had to be replaced by men. The women were called disturbers of recovery. Aside from conditions imposed by siege and occupation the German soldier is normally more free from venereal diseases than those of other nations.

When Should We Examine the Spinal Fluid of Syphilitics?—Neisser terms the examination of lumbal punctates the third of the great recent diagnostic discoveries in the domain of syphilis, the others being the recognition of the spirochete and serodiagnosis (Wassermann). Examination of the spinal fluid is now regarded as indispensable; but when ought we to use it? The author believes that with clinical evidences of syphilis, or a positive Wassermann reaction, or when the patient is doing well under treatment with no reason for its discontinuance, a test of the spinal fluid would be superfluous. But should the author deem it propitious to suspend the use of the remedy he would then as a precautionary measure make the test. Should the latter prove negative the author would feel that the patient is not menaced by the much-dreaded syphilis of the central-nervous system, and need not be submitted to further treatment. If the test is positive this usually means that nests of spirochetes are present in some of the viscera, and these may be reached by intensive treatment. These tests cannot be made at one's pleasure because the patient objects to them very strongly.

Münchener medizinische Wochenschrift.

May 11, 1915.

Treatment of War Dermatoses.—Bruck states that scabies was the chief dermatosis in the war up to December, when it yielded in frequency to pediculosis vestimentorum. Pityriasis rosea, rare at first, has since become common and is certainly connected with the use of new woolen underwear. It is certain that eczema, psoriasis, and lichen show no cumulation as a result of the war. The reverse is true of the pyodermias, which are second in frequency only to the diseases due to animal parasites. The pyodermias are caused almost entirely by the staphylococcus and include furunculosis, folliculitis, impetigo of Bockhart, impetiginous eczema, and ecthyma. Impetigo contagiosa is relatively rare, this being due to a streptococcus. The staphylococcus pyodermias yield to a vaccine preparation devised by Wassermann, consisting of a sterile extract of pathogenic staphylococci in the form of an ointment. This substance has been on trial for a year and a half, and many favorable reports have been received from well-known dermatologists who are using it. It is, of course, marketed as a proprietary with trademarked name. It not only cures but apparently confers local immunity against spreading and relapse. It is gently rubbed into the affected skin once or twice daily.

Air Embolism from the Use of Oxygen Injections in Gas Gangrene.—Since oxygen injections are indicated in lesions due to anaerobic bacteria, such as gas gangrene, it need not surprise us to find occasional deaths from air embolism. Simmons states that the resource has become popular with military surgeons during the past few months. He has had, however, a death from an embolism from its use, as follows: The soldier was shot in the leg, and it was necessary to ligate the popliteal artery on account of the profuse hemorrhage. Gangrene of the foot followed, necessitating a Gritti thigh amputation. The operation wound suppurated and gas gangrene developed. The patient was etherized and oxygen injected into the stump with sudden fatal collapse. Autopsy showed that patient had not been generally infected with gas gangrene bacilli and that the air bubbles in the right heart and pulmonary vessels had been injected from without. Simmons knows of two similar cases. Frankenthal also relates in great detail a case of the same sort. The resource will not be discontinued on account of these sporadic fatalities, but great care will have to be used. When the needle enters there should be no insufflation if blood flows.

Action of Light on the Living Cell.—Schanz states the admitted fact that light accelerates chemical processes. It transforms hemoglobin to methemoglobin, and according to its wave lengths can both change ozone to oxygen and oxygen to ozone. It assists in the production of cleavages and syntheses. Important is the subject of the influence of light on albumin, the most significant of the cell ingredients. Tests are made by placing various proteins in quartz vessels at a constant temperature of 15 deg. or 16 deg. C. An ultra-violet-ray lamp is the source of the light-rays. Rays of short wave lengths coagulate soluble albumins and render them insoluble. The question of the sensitiveness of the eye to actinic rays has long been in dispute. These are believed to cause electric ophthalmia. The lens is held to absorb a large portion of these rays as they pass unchanged through the cornea. The albumin in the center of the lens is highly insoluble. The invisible rays may therefore figure in both the physiology and pathology of the lens.

Deutsche medizinische Wochenschrift.

May 13, 1915.

Tetanus Infection and Its Abortive Treatment.—Teutschlaender relates the following case: A reservist was struck with fragments of shell on Dec. 17 and received first-aid dressings from a comrade. He slept on the battlefield, and on the following day was taken to the dressing pavilion and thence by stages to Heidelberg, which he reached on the 25th. In all he had passed through the hands of three surgeons in transit. At Heidelberg an *x*-ray was taken and a shrapnel bullet was found near the wound in the right clavicular region. He was also wounded twice in the left lower extremity, one lesion being in the knee hollow and the other somewhat above. It was necessary to cut down upon the latter to extract a shell fragment. The wound was ragged and infected and the wound tract 4 cm. long. Search was at once instituted for the presence of the tetanus bacillus, which morphologically was present, but the author omitted the mouse-inoculation test. A prophylactic injection of serum was given. The fact that tetanus did not develop is naturally indecisive. The next case to come along in which the bacteriological finds in the wound were positive was tested thoroughly with mouse control. To these animals the germs were highly virulent. The wound in this case was in the sole of the foot, and was ideal for tetanus development. Nine days after the wound local spasms developed in the foot. The wound discharge still contained abundant tetanus bacilli. Not until then was serum given. The next few days saw no change, although once the temperature started to go up. The patient escaped infection. The bacteria in the late stages of the wound were also cultivated and tested on mice, and while the latter promptly succumbed tetanus did not develop. This fact could be placed in association with failure of general tetanus to develop in the wound. Several cases on record show that wounds may be infected locally with virulent tetanus bacilli yet no general infection follows. There can be little doubt that this has even occurred in untreated wounds which have healed of themselves. Yet such cases must be rare and exemplify natural immunity. The local cramps, or so-called "traumatic spasms," may be regarded as abortive symptoms. They are also prodromes in cases which go on to infection. The danger of the latter is evidently bound up in the great resistance of the germs of tetanus. The treatment of suspicious wounds should be of the surgical-antiseptic type. Of antiseptics hydrogen peroxide and iodine tincture are mentioned.

Ecthyma, War Dermatosis.—Kromayer states that in peace times the staphylococcus is responsible for a stately array of dermatoses—impetigo contagiosa, impetigo vulgaris, folliculitides, furunculosis, sycosis, panaris, subcutaneous abscesses, phlegmons, lymphangitides, etc. To the preceding, in time of war, we can add ecthyma, which in peace is seldom encountered save in the case of decrepit children. Ecthyma constitutes 30 per cent of war dermatoses. Small pustules, scratched open and soiled with dirt, form scabs which do not end in healing. Instead pus forms beneath them and the scabs grow larger and thicker. When removed they show the presence of ill-colored granulations—veritable ulcers, which have a discolored secretion, drying into crusts composed of pus, blood, and dirt. These sores may occur in great numbers and one soldier showed no less than 172 of them, all large, nearly every part of the surface being studded with them. These seldom occur alone—furuncles and abscesses often coexist along with ordinary impetigenous pustules. Ecthyma may be regarded primarily as a filth disease. The ulcers have little tendency to heal spontaneously. The author recommends that various antiseptics be applied after thorough cleansing—potassium permanganate solution 1:4000, silver nitrate 5 per cent solution, tincture iodine, etc. The regular dressing should be boric acid ointment or dermatol. If the ulcers prove at all refractory the fine Paquelin burner should be applied.

"Plexalgia," a Disease of War.—M. Manheimer applies this term to a condition observed among French soldiers and characterized by the presence of multiple pains, sensations of numbness, general fatigue, insomnia, and excitability. This complex of symptoms is the result of the action upon the nervous system of prolonged exposure to cold and excessive humidity.—*Bulletins et Mémoires de la Société de Médecine de Paris.*

Subcutaneous Injury to the Median Nerve at the Elbow.—S. Boyd reports the case of a patient, aged eight years, who, in May, 1913, fell off his bicycle and sustained a fracture of the lower end of the right humerus, which united in good position. When he began to use the arm again it was found that he was unable to flex the thumb and index finger. He came under the author's observation in October, 1913, and was found to have paralysis of the following muscles: flexor carpi radialis, palmaris longus, flexor longus pollicis, flexor sublimis and flexor profundus to the index finger, and the superficial muscles of the thenar eminence. There was loss of excitability to faradism in the affected muscles, but no polar reversal. There was no anesthesia. The arm was put up on a metal splint with the affected muscles relaxed and regular massage was instituted. Considerable improvement ensued, and the patient can now fully flex the thumb and index finger. There is still weakness of the palmaris longus and flexor carpi radialis and some flattening of the thenar eminence.—*Proceedings of the Royal Society of Medicine.*

Purpura.—W. K. Sibley reports the case of a healthy woman, aged 27, a widow, who had never had rheumatism or any other serious illness. Thirteen weeks before, what she described as blotches appeared first on her right arm in crops which faded and left a bruise, and a moderate sized boil was present on the left breast which was painful. She had considerable pyorrhea alveolaris. Scattered over various parts of the body, especially marked over the posterior axillary folds, where they appeared in more or less parallel lines, looking like scratch marks, were numerous small subcutaneous hemorrhages of a purpuric nature; smaller ones were also present on the thighs. On the mucous membrane of the lower lip were remains of recent hemorrhages, which were also present on the palate. The patient stated that her gums bled considerably during her menstruation and often also her nose at these times. Her catamenia, which commenced at the age of 13, were usually regular and normal, but the last three periods had been severe, the last one continuing for a week.—*Proceedings of the Royal Society of Medicine.*

Insurance Medicine.

Examination in the Life Extension Institute.—In an address delivered before the Insurance Institute of Toronto, Dr. Eugene L. Fisk described the methods followed in the health conservation plan of examining the insured. The first step is for the company to inclose with its premium notices an announcement of the privilege, and a blank form for making application. On receipt of the application for examination the company forwards to the Institute a statistical card containing certain information — age, occupation, residence, etc. The Institute then forwards to the policyholder a personal history blank, calling for information regarding living habits, diet, exercise, etc.; also family history and information regarding past illnesses, disabilities, etc. This blank the policyholder fills out and presents to the examining physician, who forwards it to the Institute with his own report, a blank for which is furnished him by the Institute. The urine is forwarded direct to the Institute by the policyholder, and is examined at the central laboratory.

The total information received from these sources is then reviewed by men trained in the science of interpreting such data. The clinical findings, with the reviewer's comments, are then reported to the Director of Hygiene, who finally determines what message shall go to the individual.

A report is made to the insurance company on the statistical card by means of codes covering the various impairments. This information is held as confidential by the company, and is not interchanged with other companies. If no impairment is found the individual is so informed, or if there is a slight impairment he is told of its nature, and the report usually conveys a suggestion for its correction. If the impairment requires medical attention the report is sent to the family physician, with the individual's permission, and the latter is advised to place himself or herself under medical treatment. If he insists upon having the report direct it is given to him, but he is urged to seek medical aid.

It will be noted that the method covers more than a mere examination by the local examiner. It is a system which includes a close study and valuation of the individual as a going concern. It is essentially a health survey of every region of the body and of the life of the subject. Faulty living habits may be given more weight than an actual physical impairment. As the urine, blood, sputum, gastric contents, and feces are examined at the home office, in such cases as require it, and the personal history is given by the applicant, the system is valuable and effective, even in remote localities where trained clinicians are not available.

In the group or commercial service, an examining room is equipped in the establishment where the employees are to be examined and the work is carried on in the same manner as at the home office. Physicians are detailed to work on half-day service, alternately, until the examining is completed. All laboratory work is done at the home office, and practically the same routine is followed as in the insurance service. The following figures regarding these examinations make an interesting showing.

Results of the examination of life insurance policyholders by the Life Extension Institute: Normal, 2.40 per cent; imperfect (advice needed regarding physical condition or living habits), 97.60 per cent; not aware of impairment, 93.04 per cent; referred to physician for treatment, 65.75 per cent.

That this work is worth while and that it is consistent with sound ideals of human progress and development is shown by the following example. The head of a family is receiving an income of $5,000 per year, upon which he maintains his family comfortably. He carries, say, $10,000 life insurance, perhaps only $5,000. If he is taken away before his children reach maturity and self support the family fortune is reduced from $5,000 to $500 a year, or perhaps only $250. The life insurance covered the breach, but this man was worth to his family $100,000 valued in earning capacity alone. Add to this the priceless assets of family affection and guardianship, and one cannot doubt that the greater function is to keep this man alive, rather than to pay his debts and funeral expenses.

Accident Insurance—Evidence of Cause of Death.—In an action on an accident insurance policy issued to a railway mail clerk, the evidence showed that the insured, on leaving his car at the end of a run, gave indications of a severe pain in his abdomen. A few days later he became incapacitated, was taken to a hospital and operated upon, but died of general peritonitis. Subsequent to his first feeling ill, a yellowish spot was seen on his abdomen about the size of a half dollar and the autopsy showed that there were adhesions beneath this spot which, in the opinion of some of the medical witnesses, indicated that the spot had been caused by some external violent means, such as a blow.

The deceased was a young man and had previously been in good health. There was medical testimony that the appendix was split, and not perforated, indicating that the injury was caused by violent external means, causing appendicitis, naturally followed by the peritonitis. The deceased was alone in his car during the run. While the evidence conflicted as to some of these propositions, it was held that if the jury accepted the statements enumerated above they were warranted in drawing the conclusion that the deceased's bodily injuries were received "through external, violent, and accidental means."

The court distinguished the case of National Association of Railway Clerks v. Scott, C. C. A., 155 Fed. 92, which was an action on a similar policy, where a verdict for the plaintiff was set aside. There the deceased had been for years in ill health, suffering from albuminaria, congestion of the liver, palpitation of heart, and nephritis. The death certificate gave as the chief cause of death nephritis, and as contributing cause valvular heart trouble. The only evidence of a blow was a bruise on the shin. There was no causal connection suggested between the blow and the causes of death as in the present case. In the Scott case the theory was that because of the bruise on the shin it might be inferred that at the time it was received he had had a heavy fall, causing general shock, from which again, it might be inferred that the other ailments ensued.—Railway Mail Association v. Harrington, C. C. A., 220 Fed. 622.

Book Reviews.

Medical Ethnology. By Chas. E. Woodruff, A.M., M.D., author of "The Effects of Tropical Light on White Men"; Associate Editor of "American Medicine"; Lieutenant-Colonel, U. S. Army, Retired; Member of American Therapeutic Association; Fellow of Medical Association of the Greater City of New York; Member of the American Association for the Advancement of Science. Price $2.00. New York: Rebman Company, 1915.

The author says this book was begun as a revision of his former work on "The Effects of Tropical Light on White Men," but his title was changed because so many other factors besides pigmentation have entered into the discussion of the reasons for the differences between the present races and subraces of men.

Dr. Woodruff has made a special study of his subject, and owing to his long stay in tropical countries has been able to investigate the matter thoroughly. His experience therefore entitles him to an attentive hearing, and although some of his views are not altogether in accordance with the opinions of many tropical students, yet they are so clearly and forcibly set forth that with many they must carry conviction. It is pointed out in the chapter on racial physical characteristics that the hotter the climate in America the higher is the morbidity and mortality of the bulky man. The chapter on the effects of the infrared rays contains very instructive deductions; for example, it is pointed out that the effects of indoor heat and moisture on infants have been greatly underestimated, as they are probably more disastrous than dirty or stale milk. Dr. Woodruff's well-known views on acteriotherapy and on the relative adaptability to climate and conditions of life are discussed at some length.

The chapters on the influence of environment on infants are of particular interest. It is stated that it is now an accepted axiom that all the laws which govern the evolution of adaptation of lower animals to the environment by slaughter of the least fit and selection of the fittest, apply with equal force to man. It therefore fully explains the high death rate and their eventual extinction or change of type. The author has fortified this assertion by numerous examples drawn from many parts of the world. In the last chapter, dealing with applications of medical ethnology, it is shown how to combat successfully the maleficent influences of a change of climate and how to conserve health fairly well in an alien environment. The work is marked throughout with evidences of careful research and a considerable amount of original thought. The author not only has ideas of his own, but is able to express them in such a way that, if they do not always convince, they give one to think deeply.

Differential Diagnosis. Volume II. Presented Through an Analysis of 317 Cases. By Richard C. Cabot, M.D., Assistant Professor of Clinical Medicine, Harvard University Medical School, Boston; Chief of the West Medical Service at the Massachusetts General Hospital. Profusely illustrated. Price $5.50 cloth. Philadelphia and London: W. B. Saunders Company, 1914.

The unique character of this work, so well demonstrated in its first volume, in the discussion of differential diagnosis by the reports of typical cases and grouping these according to the preventing symptom, is again amply exemplified in the second volume. This deals with nineteen other conditions or preventing symptoms, as follows: abdominal and other tumors; vertigo; diarrhea; dyspepsia; hematemesis, glands, blood in the stools, swelling of the face, hemoptysis, edema of the legs, frequent micturition and polyuria, fainting, hoarseness, pallor, swelling of the arm, delirium, palpitation and arrhythmia, tremor, and ascites and abdominal enlargement. As in the previous volume, at the beginning of each chapter dealing with one of the above conditions or symptoms, there is a general discussion or introduction, and by means of graphic charts one can see at a glance the relative frequency of the pathological conditions which have this condition or symptom in common. These graphic charts constitute a valuable feature of the work. The case reports are concise and real; they bring one almost into the presence of the patient. Particularly valuable are the discussions under the heading of differential diagnosis; to the student of medicine and chiefly to the experienced practitioner these discussions are helpful and stimulating. The illustrations, diagrams, and charts are numerous and adequately supplement the text.

Physiological Principles in Treatment. By W. Langdon Brown, M.A., M.D. Cantab., F. R. C. P. Assistant Physician to St. Bartholomew's Hospital, and Physician to the Metropolitan Hospital, etc. Third edition. Price $2.50. New York: William Wood & Company, 1914.

In this volume will be found a summary of such of the modern advances in physiology as have a bearing on the practice of medicine. The author has been engaged in teaching physiology as well as practice, and his book contains many observations which the practitioner will find useful. Many of the gaps existing between physiology and practice are here bridged over; and whether viewed as a work on physiology or as one on practice the volume is one of unusual value. The subjects discussed are: the principles of organotherapy; the rational treatment of gastric disorders; mechanical factors in indigestion; the work of the pancreas; uric acid and the purin bodies; oxaluria, phosphaturia, and urinary calculi; albuminuria and the treatment of nephritis; glycosuria and diabetes; acidosis and intoxications; intestinal intoxications; irregular action of the heart; the vasomotor system in disease; on cyanosis; and vitamines and calcium salts. The book is provided with a good index and a useful bibliography; this latter would be of more service were it placed at the end of each chapter instead of being grouped at the end of the volume.

Diseases of the Skin. By James H. Sequeira, M.D. Lond., F.R.C.P. Lond., F.R.C.S. Eng. Physician to the Skin Department and Lecturer on Dermatology at the London Hospital; in charge of Queen Alexandra's Department for Light Treatment; Consulting Dermatologist to the Radium Institute, etc., etc. Second edition, with 48 plates in color and 238 text figures. Price $8.00 net. Philadelphia: P. Blakiston's Son & Co., 1915.

This work, as shown by its cost price, is very largely an atlas. The first edition appeared in 1911 and the increase in bulk is due in part to the addition of 60 text figures. The colored plates now include a series of microphotographs. The author states that it has been a difficult task to incorporate all the dermatological advances of the past three years, and we see at the same time notable evidences of condensation here and there. The classification shows but little change, and the number of chapters is practically the same. One of the more noticeable departures is to be found in the chapter on Diseases of the Appendages of the Skin. In the first edition forty-seven affections were described under this head, while in the present edition this number has been reduced to nineteen. A similar condensation is seen under Diseases of Microbic Origin. There are twelve additional pages on the subject of syphilis, seven on neurodermatoses, etc. To sum up, the book is an almost unique combination of text book and atlas in one volume. The illustrations, of whatever kind, are of uniform merit, and as good as the best contemporary productions of their kind.

The Modern Factory, Safety, Sanitation, and Welfare. By George M. Price, M.D., Director, Joint Board of Sanitary Control in the Cloak, Suit and Skirt and the Dress and Waist Industries, New York City; formerly Director of Investigation, New York State Factory Commission; author of Handbook on Sanitation. 8vo, 574 pages and 257 illustrations. Price $4.00 net. New York: John Wiley & Sons. London: Chapman & Hall, 1914.

This book gives a comprehensive survey of industrial conditions in factories in the United States, and an exhaustive treatment of the sanitation, safety, efficiency, and welfare work in industrial establishments in this country and abroad. The author reviews the rise and growth of the modern factory system, the various types of factory buildings, the dangers and protections from fires, the extent and causes of accidents and their prevention, conditions for lighting factories, and all the details of the sanitation of workshops. He describes the various welfare movements and practical attempts to ameliorate the conditions of working people and to improve sanitary conditions in the factory. There are chapters on the dangerous trades and industrial poisons, and on factory legislation and factory inspection. The book is a valuable compendium of information on a subject of constantly increasing importance to the social fabric as at present constituted. The numerous illustrations add much to the interest of the work.

Special Article.

THE ORGANIZATION OF NATIONAL AND LOCAL FORCES IN THE CAMPAIGN AGAINST CANCER.

By CURTIS E. LAKEMAN, Executive Secretary.

The American Society for the Control of Cancer has recently urged that every State medical society take an active part in arranging meetings and in spreading among all members of the profession the latest knowledge of malignant disease. At the suggestion of the Cancer Committee of the Pennsylvania State Medical Society, many journals will devote their July issues to this subject. It has been pointed out that the American Society for the Control of Cancer might take this timely opportunity to state its view of the relations between the various bodies which are concerned in this campaign. The suggestion is welcome. If indeed a clear understanding can be reached as to the most effective division of functions and duties among the various organizations, national, State and local, interested in this subject, a long step will have been taken toward the conquest of malignant disease, in so far as that ideal can be approached by the practical application of present knowledge.

The National Society.—The American Society for the Control of Cancer sets up no claim of priority or originality in preaching to the public the necessity of early recognition and treatment of this disease. The organization was effected under the inspiration of numerous similar movements in this country and in Europe. From the first it has been inspired only by a sincere ambition to coordinate all existing forces into a single irresistible nation-wide effort to reduce the cancer death rate by imparting the necessary knowledge and inspiring the will to believe and act upon it. Those who direct the policy of the Society have no illusions that they are "called" above others to this task. They firmly believe that all sincere workers should unite in a single well considered national movement. If the present Society fails to meet the requirements of such a movement it must give place to some agency that will do so, leading the campaign against malignant disease with as conspicuous ability and success as the National Association for the Study and Prevention of Tuberculosis has directed the war on consumption.

Relation to the Professional Societies.—While the Cancer Society found its first impulse in the work of a committee of the American Gynecological Society, the movement was broadened at its very inception by the appointment of organizing delegates from the American Surgical Association, the American Dermatological Association, the Association of Pathologists and Bacteriologists, and practically all the similar special organizations which met in Washington in May, 1913, as the Congress of American Physicians and Surgeons. Definitely launched in New York on May 22, 1913, the movement received within a few months the official endorsement of the American Medical Association, the Clinical Congress of Surgeons, the Western and the Southern Surgical and Gynecological Societies, and a number of sectional and state organizations. All these professional bodies have endorsed the design of the National Cancer Society as expressed in its Constitution:

> "To disseminate knowledge concerning the symptoms, diagnosis, treatment, and prevention of cancer, to investigate the conditions under which cancer is found and to compile statistics in regard thereto."

Relation to Cancer Research.—It will be seen that this purpose comprises not only the conduct of an educational campaign but the gathering of information in regard to this disease. In what relation, then, does the Society stand to the various American Cancer research institutions and workers? The answer is that the Society does not contemplate the prosecution or support of biological research, already so ably pursued under the auspices of our leading universities. With these workers in the field of pure science mutually helpful relations have developed. Indeed a notable collective expression of their attitude is regarded as a very cornerstone of the educational movement. A few years ago the eminent laboratory students placed on record in the transactions of their official organization, the American Association for Cancer Research, their conviction that pending the discovery of the ultimate nature and cause of cancer, a far more effective dissemination and utilization of the vast store of present knowledge of the disease is urgently called for. Formed to carry out this very object the "Control" Society depends upon the constant support and co-operation of the institutions represented in the "Research" Society. Many of the foremost American students of cancer are prominent in the membership of both organizations. Machinery is thus provided for the wider dissemination among the profession and the people of the essence of the newest knowledge of malignant disease, fresh from its laboratory sources.

Relation to Statistical Investigations.—The Society does, however, contemplate original work in the collection and collation of statistical data, and will expand this feature of its program as fast as its resources permit. The statistics of cancer mortality need to be improved both as regards their collection and their publication. The merest suggestion by the Society to the U. S. Census Bureau has been sufficient to initiate a notable advance in this respect. With the greatest possible interest and zeal, Mr. Harris, the late Director of the Census, and his successor, Mr. Rogers, have undertaken the preparation of a special report on the cancer mortality of the U. S. Registration Area in 1914. The number of deaths will be stated in full detail under some thirty titles of organs and parts of the body affected, instead of, as hitherto, merely under the six general groups of the International List. The Imperial Cancer Research Fund has long urged that it is only on the basis of such detailed data for the various organs that a true conclusion can be reached as to whether or not cancer is increasing. For the first time in the United States the data will now be at hand, as they are in England and Wales through the reports of the Registrar-General for the prosecution of such inquiries.

The Census Bureau will also for the first time in this study make a distinction between returns based on certain and on doubtful diagnosis. To secure the additional information needed for this distinction the Bureau is sending tens of thousands of letters to physicians who have certified deaths from cancer asking whether the diagnosis was based on clinical findings alone or was established by surgical intervention, microscopical examination, or autopsy.

All this, it will be realized is a large amount of work for even a government bureau to undertake. Much of it should be done in the first place by the registration offices and the boards of health of the several States, where the original certificates of death are filed. It will be the duty of the American Society for the Control of Cancer to urge upon the various State officials the need of undertaking this work in order to insure the permanence of the advance in the statistical study of cancer which has been inaugurated by the Census Bureau.

But the Society is also interested in special statistical studies of the geographical, racial, and occupational distribution of cancer, and above all in collating, upon a uniform plan, the records of surgical treatment of the disease in the leading hospitals. It is important that an authoritative answer be available for all who ask just what percentage of success is to be expected in the treatment of each phase and each stage of this multiform disease. All such studies the Society regards as fulfilling its fundamental purpose and in pursuing them it is everywhere receiving the most cordial encouragement and assistance from statistical offices and from the best hospitals and institutions.

Relation to Educational Agencies.—The important and clearly established lessons derived from such studies of the sources of information must be given to the public. The society has undertaken to do this directly, through its publications, its regular articles for the newspapers, and its lectures. But in the large view it can best secure this object by enlisting the cooperation of all appropriate existing agencies which conduct educational work. Foremost among these are the State and local departments of health, especially those which are devoting an increasing share of their energies to the spreading of the gospel of health by bulletins, exhibits, and lectures. In the same category must be included the committees on public instruction which in many States are conducting admirable campaigns of health education under the auspices of the State medical societies. Toward all these agencies the Society stands in the relation of the "producing" to the "distributing" end of a manufacturing business. With its wide outlook over the national field it is in a

strong position to provide statistical material, to receive and pass on new knowledge, new experiences, new methods which have been found valuable in one field and should be used in others. In another view the Society may take the position of "middleman" between the research workers and statistical students producing new facts about cancer at the sources of knowledge on the one hand, and on the other the many agencies, general and local, which will bring the practical bearings of this knowledge, new and old, directly home to the people. In general, then, one of the most useful functions of the Society is to act as a burden of information and clearing house which is at the service of all workers and institutions interested in the study and control of cancer.

Relation to State Committees.—The relation of the national Society to similar movements within the various States should be clear from what has been said. In no case will the Society seek to set up local agencies to parallel work already adequately organized under the auspicies of State medical societies and boards of health. Provision is made for local committees to be organized under the supervision of the resident directors of the National Society wherever no State or local agency is in a position to undertake the work. Such groups will not be formed, however, except under full agreement with present State agencies. Where, as in Pennsylvania, under Dr. Wainwright, and similarly under the auspices of State medical societies in Maine, Wisconsin, Kansas, Colorado, Louisiana, Texas, and many other States, active local committees are at work, every effort will be made to assist these groups in the manner already outlined and so far as the constitutional limits of size permit to secure from them representative delegates to the governing council of the National Society. At least one director from each State will eventually be chosen to act as a local correspondent who will inspire and stimulate work in his own State while at the same time assisting in formulating the general policies of the National Society.

Relation to other General Committees.—It is an earnest of the good feeling and harmony with which the cancer campaign is evolving toward a single coherent national movement to consider the high degree of integration with other national agencies which has already been attained. Some of these had begun effective work long before the present Society was established. Aside from such admirable local campaigns as that of the Pennsylvania Commission and the work inspired by Dr. C. C. Carstens in Michigan, the Clinical Congress of Surgeons of North America had in the field an active Committee on Cancer under the chairmanship of Dr. Thomas S. Cullen of Baltimore, the other members being Dr. Simpson of Pittsburgh and Dr. Howard C. Taylor of New York. This committee, as is well known, caused the publication of widely read and influential popular articles by Samuel Hopkins Adams. It is instanced merely as indicative of the get-together spirit that animates the National Society that all three of these men naturally took their places as members of the Executive Council of the new association. Subsequently the American Medical Association appointed a cancer committee representing its council on Health and Public Instruction, and again to avoid duplication of effort the same men were made members of that committee. Dr. Frederick R. Green, the capable executive of this Council of the American Medical Association, has been from the first a director of the Cancer Society, and has given invaluable advice and co-operation in its publicity campaign, printing every week in the press bulletin of the A. M. A. a popular article on cancer prepared by the Society, which thereby reaches 3000 or more editors in all parts of the country.

A similar identity of committees has been effected in local fields, especially in Minnesota, and is typical of the desire to carry on everywhere a well-coordinated national campaign which shall embrace representation from all the principal local agencies and shall thus move forward with absolute harmony and unity of purpose to the accomplishment of its difficult but glorious ideal—the progressive reduction of the mortality from this historic scourge of mankind.

Rumination and Pylorospasm.—E. Aschenheim reports two cases in which these conditions were associated. The primal causes were held to be pathological reflexes and a neuropathic disposition.—*Zeitschrift für Kinderheilkunde.*

Society Reports.

AMERICAN MEDICAL ASSOCIATION.

Sixty-sixth Annual Session Held in San Francisco, Cal., June 21-25, 1915.

(Special Report to the MEDICAL RECORD.)

(*Concluded from Vol. 87, p. 1093.*)

COMMEMORATION DAY EXERCISES.

Wednesday, June 23, 1915.

WILLIAM L. RODMAN, M.D., OF PHILADELPHIA, PRESIDENT, IN THE CHAIR.

THE Board of Trustees of the American Medical Association set aside this day as Health Conservation Day in recognition of the service of the men whose contributions to sanitary science and preventive medicine had made possible the construction of the Panama Canal, and in commemoration of the progress of medicine which had resulted in the betterment of conditions of human life. All the Sections of the Scientific Assembly cooperated in the observation of Commemoration Day and held no section meetings. The addresses given by experts in the fields they represented were designed to show the origin and evolution of preventive medicine from scientific foundations and to make plain the benefits which had come and were yet to come to the world from the application of such scientific knowledge. Since the audiences included many who were not of the medical profession the speakers presented their subjects in simple language suited to such an occasion.

Dr. WILLIAM L. RODMAN in opening the meeting, said that the building of the Panama Canal from the standpoint of engineering was not so difficult a task. The attempt to build a canal had been made before but failed because of the prevalence of yellow fever and Chagres fever which could not be controlled until modern medicine had shown the way. He quoted from an address of ex-President Taft's on the value of the sanitary work of the United States in Cuba, Panama, and the Philippines to the effect that while he could not speak with absolute certainty as to the political and educational benefits conferred on these countries by the United States, he was thoroughly convinced of the blessings conferred on those countries by the sanitary work done by the medical men of the United States Army and Public Health Service. No better illustration of this could be given than the facts in connection with typhoid fever in the army. In the Spanish war 90 per cent. of the volunteer troops had the fever while a few years ago, after vaccination against typhoid fever became a routine procedure in the army there was not one case of typhoid fever among the troops sent to the Mexican border, excepting in the case of one man, a teamster, who refused to be vaccinated.

Infection and Immunity.—Dr. VICTOR C. VAUGHAN of Ann Arbor made this address in which he said that it had been the habit of the human race to look upon epidemic disease as due to an angry God avenging their sins, or if sickness and death came to them personally they said "Whom the Lord loveth he chastiseth," and were resigned. Another theory of disease was that of Hippocrates who promulgated the miasmatic theory of disease and reasoned that if a large number of people became affected the cause must be something that reached all the people and therefore it must be the air. This idea had come down many centuries and even today influenced their ideas. Even as late as the Spanish war there were those who, with bated breath, said that the fever in the camp at Chicamaugua was not typhoid fever but Chicamaugua fever. Other instances might be cited in our own time showing that locality was supposed to be responsible for disease. Our modern view of infection had its inception with Pasteur, who began to work on the phenomena of fermentation and proved that this was due to living organisms, and that each kind of ferment had its own specific organism Many had confirmed his findings and theories. Robert Koch developed the ideas of Pasteur and we now knew that every infectious disease was due to a specific organism, and that these organisms were living bacteria. A few bacteria caused disease because of the poisons they elaborated. Such diseases were tubercu-

losis, tetanus, botulus, etc. There were some widely prevalent ideas concerning bacteria which in his opinion were quite erroneous. It was generally stated that bacteria were low forms of plant life. Plant cells, generally at least, contained cellulose; bacteria did not. Plants under normal conditions took in carbonic acid and gave off oxygen; bacteria absorbed oxygen and gave off carbonic acid. Many thought that bacteria contained no nuclei but it had been shown that they were composed almost wholly of nuclein. Functionally bacteria were highly developed. It had been thought that pathogenic bacteria alone developed poisons but it had now been shown that non-pathogenic bacteria developed as much poison as the pathogenic. The fact that determined their pathogenicity was their capability of growing and multiplying in the animal body. They next found that there was as much poison developed in animal protein as in bacteria. One gram of casein might generate enough poison to kill 8,000 guinea pigs. They then tried to find whether poisons were present in vegetable proteins. It would be interesting to his friends, the vegetarians, to know that there was as much poison present in vegetable protein as in animal protein, and they were just as deadly. Whether bacteria grew in an animal depended on their ability to feed on that animal, and on the ability of the animal cells to feed on these bacteria. Nothing could assimilate without digestive ferments and these were specific in action. The prodigiosus was non-specific because it could not eat and digest the proteins of man's body and the ferments of man's body digested the ferments of the prodigiosus. They had also learned that the ferments of the cells of man's body could be altered so that bacterial cells that under normal conditions would not be digested by the body cells could, under other conditions, be digested. This was the principle upon which vaccination was based. After speaking somewhat further of typhoid vaccination and of the work of Jenner, Dr. Vaughan showed that the effects of the great discoveries of modern medicine had greatly lengthened the average span of human life. If they would go back to 1880, the first time an accurate census was taken, and compare the figures with those of the present time it would be found that the average duration of life had increased ten years since 1890 and it was stated that in the last decade it had increased four years. In the middle ages, so far as could be estimated, the average duration of a human life was 20 years. This estimate was made from Statistics of London during the latter part of the fifteenth and sixteenth centuries. In 1880 in this country the average duration of a human life was thirty years and today it was forty-two years. The mortality rates of the United States were lower than those of Europe and the average of human life was longer and if this was true two other facts were true: the average intelligence was greater, and the efficiency of the medical profession was greater in this country than in any other. If the people of the country as a whole would put into operation such sanitary rules and regulations as General Gorgas had formulated and applied in the Canal Zone, the average life of our children would be sixty-five years. This was a matter in which they should all interest themselves since sanitation was the keystone and the triumphal arch of civilization. If for one month the sanitary rules and regulations under which large numbers of our people were living in our cities, and especially in San Francisco, were abandoned we would see an epidemic such as had not been seen since the middle ages. Dr. Hoffman of the Prudential Life Insurance Company had stated that if the same conditions with reference to tuberculosis existed since 1901 as had existed before that time, there would have been 200,000 more deaths from tuberculosis than had actually occurred. This was a great achievement and they counted their victories, not like those of the battlefield by the number of lives lost, but by the number of lives saved. In closing, Dr. Vaughan urged that all join with them in this great work. They were learning that riches and honors and learning were of small value in comparison with health and though he hoped such a thing would not come to pass, it might be that the time was not far distant when we would need the strength and vigor of the country in order to maintain our existence.

In the absence of General Gorgas, Dr. Rodman spoke further of his work in the Canal Zone and introduced Col. Arthur of the Medical Corps of the United States Army.

Personal Reminiscences of Surgeon-General Gorgas.—Colonel WILLIAM H. ARTHUR, Assistant Surgeon-General, U. S. Army, spoke informally, stating that sending him to take the place of General Gorgas was like asking for a steam shovel and being given a pewter teaspoon, but that he was glad of the opportunity of bearing witness to General Gorgas' noble and lovable qualities and of congratulating the civilized world on the work he had done. He then gave an account of his personal acquaintance with General Gorgas since 1895, when he studied with him at the New York Polyclinic Hospital. He recalled the way in which Dr. Gorgas applied the scientific knowledge that had been gathered by Reed, Carroll, Lazear, and Agramonte to the practical work of cleaning up Cuba and Panama, and attributed his success to the fact that he could not be discouraged, and to the patience with which he awaited the opportunity to carry out a work in which he was interested.

Cancer: Its Prevention and Cure.—Dr. WILLIAM J. MAYO of Rochester, Minn., read this paper. He said that while Professor Vaughan's paper dealt with saving the lives of thousands, his dealt with saving the individual. The disease was prevalent enough to be classed as a scourge. Statistics showed that the disease was on the increase, but this increase was relative, probably, rather than real. The average length of life in the last decade had increased by 15 years, thus augmenting the proportion of individuals at the "canger age." Another point was the improvement in modern methods. Cancers exposed to the eye showed no increase, but rather those internal ones, exposed by the surgeon's knife and the Roentgen ray. An important question, often asked, was concerning the heredity of cancer. This had not been proven, but one could say that tissues liable to be attacked by cancer might be inherited, and individuals would more readily contract the disease. Life insurance companies did not take cancer heredity into consideration. Was cancer contagious? Not, as far as known, from one person to another, but it was contagious in the same individual. Heterogeneous grafting took place in mice, but homogeneous grafting had failed, while autografting certainly took place. Metastases took place at a point distant from the primary lesion, carried in the direction of the lymph stream. Was there anything in the tales of "cancer houses" and "cancer towns?" This excess was relative, not real. Towns called "cancer towns" were found to be those from which the younger population had migrated, leaving a larger proportion of "cancer age" individuals. Cancer houses were accounted for by the "mathematics of chance." The question of etiology of cancer found two groups of adherents; first, those who believed that certain cells had the properties of growth and repair. These cells, were, so to speak, "set on fire." The question then arose, "What set them on fire?" Secondly, there were those who believed cancer to be parasitical. This theory was mainly upheld by Erwin Smith's experiments on plant cancer. One main feature of cancer was that it never appeared of itself. There was always a primary lesion, resulting from trauma, injury, or infection. The precancerous lesion appeared before the cancer. A change appeared in the cell, which became like an embryonic cell, but still the cell kept its natural position. Later the position also changed. All vertebrate animals suffered from cancer, produced in some way by the habits of the animal. Thus in Denmark, Danish rats in the sugar refining houses, did not suffer from cancer, but American rats imported into Denmark, did so. The reason for this was found to be that American rats ate cockroaches, in which were trematodes which bored into the mucous lining of the stomach, causing cancers. Other cases were equally demonstrable. Thus, draft cattle, whose horns were bored for a rope to draw loads, developed cancer at the base of the horn. Chinamen, whose scalps were customarily shaved with a blunt razor, developed cancers of the scalp. In India and the Philippine Islands where the betel nut was carried next the gum and chewed, 85 per cent. of cancers were of the buccal mucous membrane. Australian ulcer was caused by sunburn, irritated by certain sand. Chinamen who ate hot rice, developed cancers of the pharynx, while the female, who ate later and got her food cold, was immune. The smokers' cancer in America was well known, and in this respect the American women were catching up with the men. Thus cancer was always preceded by chronic irritation. The cure consisted in

the early removal of the precancerous lesion. Cancer in the early stages was a local disease. If removed then it was certainly curable. The general pessimism relative to cancer had one definite reason. The persons who had been cured by surgical interference, did everything to conceal the fact that they had suffered from cancer, while those who were incurable could not hide the fact. Certain people, however, who had chronic spots of irritation, did not develop cancer, showing that there must be a certain immunity. Work of the future would be developed to increase this immunity, and it was even possible, that, without knowing directly the cause of the disease, one could, by increasing immunity, prevent the development of cancer.

Syphilis as a Modern Problem.—Dr. WILLIAM ALLEN PUSEY of Chicago presented this subject. Dr. Pusey stated that from the standpoint of medicine, syphilis was a preventable disease. The problem was now one of sanitation. In recent years the most important problems had been solved. Beginning with 1903, when Metchnikoff and Roux had demonstrated that syphilis was inoculable in animals, other important discoveries had followed: the discovery of *Spirochæta pallida* by Hoffmann and Schaudinn in 1905; the application of serum diagnosis of Bordet and Gengou, by Wassermann in 1906; the prophylaxis of syphilis of Metchnikoff and Roux in 1906; the discovery of salvarsan by Ehrlich in 1907; and the cultivation, and reproduction in animals, of *Spirochæta pallida*, by Noguchi in 1911. Immediate practical benefits had followed these important findings. Since the practical use of salvarsan the danger of infectivity to the community had been minimized, and this with Metchnikoff's personal prophylaxis, were the best aids in this great problem of modern society. This disease occurred in man alone and infection only came about by direct contact with infection, in parts not protected by skin and mucous membrane. A break in the surface was necessary to contract infection. A sanitary attack could be made from two directions: limitation of time of infectivity and protection of the healthy from the infected. Quarantine, as for acute infections, was impossible with a long-standing disease like syphilis; therefore the course of infection must be shortened. If patients infected could be treated within two weeks of infection, in 95 per cent. of cases the disease could be stamped out immediately. Even in 6 weeks the further course could be made almost negligible. With intelligent treatment the percentage of the disease could be reduced one-third. Treatment on a large scale by the State was possible, as the early syphilitic was an ambulant case who could come to the dispensary for treatment. Such dispensaries should be fully equipped to give free treatment to large numbers. To ignore such cases constituted a public danger. The medical profession needed training in early diagnosis, and systematic prevention, as had been carried on for years in Scandinavian countries, should be inculcated. This was far more possible now with mercury and salvarsan treatment. Such a procedure involved no complex sociological or moral questions, such as the segregation of syphilitics, or legal recognition of prostitution, which latter idea would never find foothold in Anglo-Saxon communities. The only adequate sanitary attack was to protect the public from the infected. It was unfortunate to view the syphilitic as suffering from his own fault, and therefore to be ignored. This involved danger to the innocent. The Metchnikoff and Roux prophylaxis consisted of a 33 per cent. calomel ointment applied to the site of infection. This plan had been used in the army and navy with remarkable result. It also protected doctors and dentists in the exercise of professional work. This prophylaxis had been wrongly regarded by some as an encouragement to lax morality, but morality, guarded only by fear of syphilis, must soon fall to the ground. The method must be regarded as rational as the prevention of yellow fever by control of mosquitos. The main problem was a sanitary one, but education of the child and the young adult as to the dangers of venereal disease was also essential. The social problem of late marriage was a serious one in the control of syphilis. An economic system which made it impossible for young men to marry was dangerous to the community. The sexual appetite, after hunger, was one of the strongest factors in human action, and, biologically, no plan was possible which attempted to control disease by controlling the sexual appetite. The control must be a sanitary one. This was the state of the problem which the syphilographer had to offer to the public.

The afternoon of Health Conservation Day was devoted to popular lectures given by well known experts and illustrated by lantern slides and motion pictures on malaria, yellow fever, dysentery, typhoid fever, plague, hookworm, leprosy, tuberculosis, syphilis, gonorrhea, pellagra, rabies, epidemic cerebrospinal meningitis, poliomyelitis, pyorrhea alveolaris, and trypanosomiasis.

In addition the Board of Trustees of the association had placed an exhibit in the Palace of Education of the Panama-Pacific International Exposition showing the activities of the Propaganda for Reform Department of the *Journal*, the work of the Council on Medical Education, and of the Council on Health and Public Instruction. There was also an exhibit calling attention to certain facts relating to patent medicines for the purpose of presenting the truth to the public rather than to the members of the profession.

SECTION ON DISEASES OF CHILDREN.

Thursday, June 24—Second Day.

Dr. LAWRENCE T. ROYSTER OF NORFOLK, VA., IN THE CHAIR.

Craniometry in Diseases of Children.—Dr. G. HARDY CLARK of Waterloo, Iowa, presented this paper and demonstrated the method of using the instrument which he described. He said it was difficult with our present knowledge to make any statements as to the value of craniometry in the diagnosis of disease. Any advance must be based on the acceptance and use of a simple method of measurement. The craniometric points on the dry skull were very difficult to adjust and use. It was desirable to have a base line extending from the glabella to the inion as a foundation which met the requirements of craniometry in that it might be set at a definite angle. If it was desirable to establish the facial angle upon a plane parallel to the cerebral base line this could also be done. A lead tape was used to make a record of the profile of the skull. The height of the cranium above the base line at any point could be ascertained. This instrument would make many comparisons of skulls possible. As the skull underwent rapid changes in early life this instrument would be helpful in determining the amount of the changes and should give information of value in the diagnosis of diseases and in determining the effects of mental training and character development in health subjects. The latter the author considered of considerable importance as the development of mentality and character in a race was coincident with symmetrical cranial lines and generally speaking the occurrence of abnormally sharp curves or flat surfaces appeared to predominate in individuals who were least efficient as factors in social progress.

Dr. J. P. SEDGEWICK of Minneapolis said Dr. Taylor was making some studies of a similar nature at the University of Minnesota. He related the case of a child with a high vertex suggestive of oxycephalia. The child died when two months of age and at post mortem was found to have an aortic stenosis and a patent ductus arteriosus. The question came up whether the increased vertical measurements had anything in relation to this condition of the heart. The instrument might be useful in giving them some information in regard to other conditions aside from oxycephalia, anacromegaly, and conditions of that class.

Dr. C. G. GRULEE said he had seen a case somewhat similar to Dr. Sedgewick's, but there was no heart lesion. He thought that to be able to get measurements and to study skull deformities would be a distinct advance.

Dr. HENRY DWIGHT CHAPIN of New York said he had made a study of bone development and mental condition in the New York Juvenile Asylum some years ago and they had not found that the shape of the skull bore any direct relation to the mentality. The brain would tolerate and adapt itself to any condition of the skull if it were slow in developing.

Dr. J. A. COLLIVER of Los Angeles said he had been associated with juvenile court and made a study of the effects of tobacco on young boys, but found nothing that was particularly characteristic accompanying its use in these boys. The size of the skull did not seem to have any relation to the use of this narcotic, at least it had seemed impossible to come to any definite conclusion.

Tuberculin Tests in Children of Colorado.—Dr. GEORGE H. CATTERMOLE of Boulder, Col., read this paper

in which he said that most of the available statistics on the prevalence of tuberculosis among children were derived from studies made in the hospitals and dispensaries of large cities. There seemed to be no data derived from private practice or observations made on school children living in small communities. In his series of 132 tests made on 110 persons, sixty-nine of whom were under fourteen years of age, using the von Pirquet and Morro tests, 38 per cent of the children gave a positive reaction; 41 per cent were negative. Fifty per cent of these children had parents who suffered from active tuberculosis. In summarizing the essayist said that where children had never been infected or in cases in which the number of bacilli received was small and the child's resistance good, as in Colorado, they did not react and were either not infected or were immune. In this series of cases there seemed abundant opportunity of infection and he believed that many of the children were immunized, though this point required further study. Possibly all tuberculosis was contracted in childhood and from three-sevenths to six-sevenths of the population acquired immunity at this time while the others succumbed to the more acute conditions of childhood or later developed pulmonary tuberculosis. In the prevention of tuberculosis one should aim to protect infants from all sources of exposure and older children from massive infection. Moderate and gradual infection in older children probably insured immunity.

Dr. E. C. GRULEE emphasized the fact that the large proportion of infections with tuberculosis were from individual to individual. Such infections far exceeded the infections from milk.

Dr. LANGLEY PORTER of San Francisco called attention to the fact that many children were infected from their grandparents, since these old people with persistent winter cough and chronic asthma, so-called, usually had tuberculosis.

Dr. HENRY D. CHAPIN of New York said he thought it was well not to put too much emphasis on the danger of bovine infection since it might scare persons so that they would be afraid of using milk. This would be unfortunate since milk was so essential in the treatment of tuberculosis.

Dr. ERNEST LACKNER of Chicago said he had been agreeably disappointed to find that in a series of 400 children from the Ghetto only about 20 per cent responded positively to the von Pirquet test.

Dr. J. I. DURAND of Seattle said that Dr. Manning had found only 22 to 23 per cent of a group of children in Seattle reacting positively to tuberculosis. One reason why more of Dr. Manning's children did not react to the tuberculin test might be because they had been making such a vigorous campaign against tuberculosis in Seattle. When they found a child with tuberculosis positive von Pirquet in the clinics they examine the parents and in this way were able to get a number of cases in the early stages.

Dr. T. C. MCCLEAVE of Berkeley said they all acknowledged that the largest proportion of tuberculous infections in man were of the human type, but the reason many had objected to even a reference to the bovine type was because they feared it would distract attention from the human type wherein the greater danger lay. They were now outgrowing this attitude of mind.

Quantitative Determination of Nitrogenous Elements in Newborn.—Drs. F. W. SCHULTZ and C. J. PETTIBONE of Minneapolis presented this paper in which they had tabulated the results of the quantitative determination of some of the nitrogenous elements of the blood of the newborn and compared these figures with some of those obtained in adults. By the newer methods these estimations could be made with from 15 to 20 c.c. of blood. After reviewing the views which Slyke and Meyer had formulated as to the fate of the protein digestive products in the body and referring briefly to the findings of Schondorf, Farr, Austin, Folin, Delaunay, Abderhalden, and others, they stated that their series of cases numbered twenty-six infants from one to ten days old. A review of their different results showed that the total nonprotein nitrogen per 100 c.c. of infant's systemic blood was approximately the same as in the adult. The age and weight of the infant and the period after feeding had no bearing. The percentage of urea nitrogen was uniformly high and averaged about 50 per cent of the total nitrogen. It was lowest in a newborn infant one-half hour old and in the cases that had not been fed. The amount of ammonia nitrogen was extremely small in every instance and was also not influenced by the age of the infant or the time after feeding. Probably the most interesting fact brought out was that aminoacids were constantly present in appreciable amounts in the infant's blood and were found shortly after birth when no feeding had as yet been given. It could hardly be said that the changes in the non-protein nitrogen in the systemic blood reflected the stages of protein digestion.

Dr. LANGLEY PORTER of San Francisco said he did not think they should let this paper pass without some discussion. He felt that with some training it would now be possible for them to use this method and that it might help them to solve some of the questions that would come up in pediatrics.

Dr. SCHULTZ said he had forgotten to mention one interesting thing that had come up in work of Osborne, Mendell, and Lusk, and that was that the feeding of aminomacids enabled them to sustain life for a considerable length of time in animals and the introduction of elementary aminoacids seemed to stimulate proteid metabolism.

Epidemic Abortion Reactions in Children.—Dr. J. P. SEDGEWICK and W. P. LARSON of Minneapolis presented this paper, in which they reviewed some facts with reference to the occurrence of epidemic abortion in cattle. It had been found that the *Bacillus abortus* occurred in a number of species of animals and was probably more common in man than had been supposed. After relating the results of some of the laboratory experiments on animals with reference to their reaction to injections of the *Bacillus abortus*, the authors stated that they had been using the complement fixation test, using the *Bacillus abortus* as an antigen. In the course of their investigations they had examined the blood of puerperal mothers, newborn children and children with bone lesions and other diseases. This form of infection was found more often in the children of the poor who were using ordinary store milk. The symptoms were quite similar to those of tuberculosis, and it had been found a number of times in newborn infants and in children with bone lesions. In two instances women on farms where the cattle were suffering from epidemic abortion aborted. The *Bacillus abortus* in the cases coming under their observation was found oftener than a positive Wassermann reaction.

Cerebrospinal Meningitis During the Texas Epidemic of 1912.—Dr. J. S. BARDIN of Fort Worth, Texas, read this paper, in which he reviewed a series of eighty cases of cerebrospinal meningitis, nearly all children, which he had treated during the epidemic of 1912. He said the disease was regarded as infectious and contagious and was quarantined. He had had a mortality of 18¾ per cent. It was not observed that weak and delicate children were more prone to infection than the well nourished and robust child. It had been noticed that epidemics in Texas had occurred with the beginning of cold rains following a series of dry years with especially mild winters. Sporadic cases occurred in which there was no evidence of exposure. The germ seemed to be every where, but only a small percentage of persons were susceptible to the infection. In most of their cases the characteristic symptoms were present, and the diagnosis was easy. There was some unusual cases that might have been taken for intestinal autointoxication or malaria. There were two symptoms which aided materially in the early diagnosis of the disease and these were the "meningitis moan" and the "meningitis expression." The moan differed from the cry of hydrocephalic patients in that it had a certain degree of regularity and was decidedly characteristic to one who had become familiar with it. The facial expression of the early stage of the disease was difficult to describe, but was likewise characteristic; there was a loss of luster of the eyes and often the absence of conjunctival reflexes. There was usually a pinched expression with cyanosis. It was their custom to puncture every case, and if the fluid came away under pressure to administer serum in every case. The duration of the disease was very variable. Most cases that recovered made a perfect recovery. The cases of spotted fever invariably died. They had no absolute rule for giving the serum. They had to be guided by the symptoms as to the number of punctures and the length of time between the same. They had some relapsing cases, but these all recovered. They had found blood pressure observations during puncture impractical and of no value. The condition of the respiration was their most important guide during the procedure of puncture. The syringe method of injecting the fluid was preferred. In posterior oasic

meningitis direct puncture of the ventricles might be done, but he had had no experience with this procedure. They had done a lumbar puncture in all cases, and the time between the punctures had varied from six hours to two weeks.

Dr. HENRY DWIGHT CHAPIN of New York said that in his experience with reference to the mortality in spinal meningitis he had found that if the patient could be kept alive for ten days or two weeks he would probably get well. For this reason proper nourishment was very important. Another point was that they did not seem to get the large effusions of blood now that they used to see in the cases that they called "spotted fever." They used to see very large ecchymoses, but now if they saw this condition the spots were only pin points. In his experience the gravity method of injecting the serum had been a little safer than the syringe method. The serum should be administered very slowly, taking ten or fifteen minutes to introduce it.

Dr. LANGLEY PORTER spoke of meningitis as he was seeing it in California. He thought the cases could be divided into two types, one in which there was increased pressure and one in which the pressure was not greatly increased and the fluid was thick, tenacious, and gluey, the symptoms in such cases being due to toxic and irritative cord conditions. He spoke of puncture of the corpus callosum in cases in which the aqueduct of Silvius was closed, which would allow the fluid to escape into the subdural space.

Dr. J. S. BARDIN of Fort Worth, Texas, said someone in discussing the paper had spoken of dry punctures, and his experience had led him to be very suspicious of dry punctures. If one did not get fluid down low he should go up higher, for sometimes the fluid might be walled off higher up in the canal. He cited one case in which he was unable to get fluid, and punctured the ventricle and the child got well.

Involvement of the Urinary Tract as the Result of Focal Infection in Children.—Drs. CLIFFORD G. GRULEE and F. W. GAARDE of Chicago presented this paper, in which they related the history of six cases in which a focal infection in some distant part of the body seemed to be responsible for affections of the urinary tract. In most of these cases the urinary symptoms developed six or seven days after the onset of a severe tonsilitis. The findings in the urine included hyaline and granular cast leucocytes and red cells. In several instances an organism was isolated from the urine similar to that found in the focal infections and this suggested an etiological relationship, between the focus of infection and the urinary disturbance. The amount of prostration was slight, and the condition tended to rapid remission. The treatment had been urotropin and sodium bicarbonate. The striking feature was the rapidity with which the urinary condition cleared up after the focus of infection was removed in several of the cases.

Dr. WALTER D. LUDLUM of Brooklyn said that the small doses of hexamethylamine which Dr. Grulee used were not sufficient, in his opinion, to have any effect. He was in the habit of giving very much larger doses as a urinary antiseptic .

Dr. F. C. NEFF of Kansas City said it seemed to him that the point of this paper was that when they had made a diagnosis of one condition they should not be too ready to conclude that that was the only trouble, but should look for the primary source of infection.

Dr. L. T. ROYSTER of Norfolk said he would like to ask if any one had gotten any results with vaccines and whether they had used sodium phosphate for acidulating the urine. The urine should be examined in every case of infectious diarrhea since there might be a colon bacillus pyelitis.

Dr. GRULEE, in closing, said that perhaps Dr. Neff's theory with reference to the large doses of hemamethylamine was correct, but it did not work out in practice. More than two or three grains were not necessary since it was not broken up in more than certain amounts. It was very difficult to prove that we do or do not get results in these cases, but I know the findings in such cases clears up gradually after small doses.

Mental and Physical Survey of Suposedly Normal Children.—Drs. LANGLEY PORTER, A. HUFFAKER, and A. RITTER of San Francisco, presented this communication, consisting of data based on the study of 195 children, all over two and one-half years. These children were cared for at the Agency Baby Clinic by R. Holsclaw and Dr. Rude and were boarded out by the Children's Agency of the Associated Charities. Each child was given a thorough physical examination, a Binet mental test, and Healy psychological test. The Wassermann and von Pirquet tests were also done. It was found that 55 per cent of these children were in need of dental care and 53 per cent had diseased or hypertrophied tonsils. Only four cases showed a positive Wassermann reaction. The children were classified as normal, retarded, borderline, moron, and imbecile. The most interesting groups were the retarded and borderline cases. In the retarded group were placed those who did not test up to age, but whose environment and health conditions might be responsible for their temporary retardation. Such cases must be sharply differentiated from the feeble-minded group as one would do an irreparable injury by committing a child to the feeble-minded group. Into the borderline groups were assigned those cases which were not normal, though they might seem normal intellectually, but whose environment was bad and training often vicious, and whose mental equilibrium was limited during the development period. Most delinquents fell into this class and might be prevented from becoming criminals by careful supervision and guidance. Following this classification they had found that the absolutely normal children comprised almost 66½ per cent; the retarded about 23 per cent; the borderline about 7 per cent; the morons, 4 of 119 cases, which were subjected to the psychological tests. On the physical side the most interesting fact was the high proportion of children who showed evidence of involvement of the tracheobronchial lymph glands, while only five cases showed the usual symptoms of involvement of the lung with tuberculosis. Eighteen children showed involvement of the mediastinal gland as was confirmed by radiograms. In this connection they had investigated Ewart's, von Koryani's, and Oespine's signs and their experience had led them to attach great value to the latter. This was an echoed whisper following a spoken word heard in the stethoscope placed over the seventh cervical and first or second dorsal spine. They had also studied whispered pectoriloquy over the spine and had found that it ran quite parallel with the dullness. They found in well-developed cases of mediastinal evolvement, but that it was a much earlier and more delicate sign than any other yet brought to their notice. The *x*-ray had shown infiltration in every case showing this sign. Ear complications and eye defects were very rare. Nine per cent showed tracheo bronchial adenopathy which would be interpreted as tuberculous by many clinicians and which was probably tuberculous in a large proportion of the cases.

Dr. EMMA MERRITT of San Francisco, called attention to the posibility of enlarged bracheobronchial lymph nodes as a sequellæ of whooping cough. She said that Jules Seamen in the clinic of Les Infants Malades in Paris had called attention to this thirty years ago. While there was no *x*-ray at that time, from auscultation and percussion and the knowledge gained at autopsies, they had been able to learn a great deal about these enlarged glands and they would sometimes remain for a number of months, but they were probably not tubercular.

Dr. A. HUFFAKER of San Francisco, described in detail the method of bringing out the pectoriloquy and of detecting enlarged mediastinal glands. Where the signs indicated the existence of enlarged mediastinal glands the *x*-ray should be used to confirm the diagnosis so that the patient might receive appropriate attention.

Dr. A. J. COLLIGER of Los Angeles, said he had examined in the neighborhood of 2500 and found accidental heart murmurs in 20 per cent of the cases. The examinations were made about the age of puberty, then again one or two years later, when it was found that 75 per cent of the murmurs had disappeared. He believed that efforts directed to the correction of physical defects caused a decrease in the amount of delinquency.

Starch Digestion in Children, with Some Clinical Observations.—Drs. H. H. YERRINGTON and CLYDE T. WETMORE of San Francisco, presented this paper in which they reviewed the physiology of starch digestion and showed that many children were suffering from excessive amount of starch. During the last four or five years in the out-patient clinic of the Division of Pediatries at the Stanford Medical School they had been making a routine examination of urine and stools in the majority of cases, especially in those having intestional disorders, and in all cases examined for tonsil and adenoid operations. There was a certain type of child

whose dietary was made up principally of carbohydrates and whose stools showed an excess of undigested starch. They had examined 372 stools from 338 cases ranging from one to fourteen years. The diagnosis varied, but there were 267 cases of hypertrophied tonsils, 41 of digestive disturbances, 10 of eneuresis, six of ricketts, and 14 of other conditions, including bronchitis and skin conditions. The greatest percentage of starch excess was found in the cases having digestive disturbances and next was rickets. They concluded that there was a type of indigestion in children presenting certain clinical manifestations brought on by the continued use of a diet compound, principally of carbohydrates, that this condition could be cured by eliminating starches and giving a mixed diet at proper intervals. Frequent examination of the stools was absolutely necessary to aid in the diagnosis and check up the progress of the case. Before attempting to correct the dietary errors of the oral cavity should be corrected. Chronically inflamed tonsils and nasal secretions played a most important part in relation to the proper digestion of the child's food.

Casein Milk Feedings in Infancy and Childhood.—Dr. WALTER GELLHORN of Seattle, presented this paper, in which he described his method of preparing a casein milk. He stated that his observations conformed pretty closely to the experience of the authors who favored the use of casein milk, but he had found that he could improve results by making not only the carbohydrates but also the fats a variable constituent. Miller and Hoobler had published similar views. They had used the powdered casein which Hoobler recommended in the county hospital and had found it just as valuable as any other preparation. The modification was made of 4 per cent milk, and consisted of 17 ounces skimmed milk, 1½ ounces of cream (top), 17 ounces of water, three level teaspoonfuls of plasmon. This was boiled. The caloric value after adding 5 per cent dextro-maltose amounted to about 440 calories per 1000 c.c. It contained only about one-half as much fat as albumin milk, two-thirds of its calcium and 0.8 per cent more lactose. In severe cases the sugar was not started until the third or fourth day. The fats and sugar could be increased as the patient became able to take care of adidtional amounts. The report was based on the experience of the writer with this food in 163 cases, not hospital cases.

SECTION ON SURGERY.

Thursday, June 25—Third Day.

Fascial Tubulization in Repair of Nerve Defects—An Experimental Study.—Dr. DEAN D. LEWIS of Chicago read this paper. A number of different materials had been used to prevent the action of scar tissue on the injured nerves and to form tubes through which neuraxons developing from the proximal stump could be conducted to the distal end of the nerve in cases in which there had been an actual loss of substance. Foramitti's hardened calves' arteries and veins were probably the best to date. They were slowly absorbed and did not provoke scar tissue. Best results in transplantation were obtained by using autogenous materials. Lewis said he used fascia late in tubular formation. Had experimented upon 40 dogs, using the sciatic nerves. Killed them from one day to 14 weeks and made histological specimens of the most of them. He believed microscopical study was after all the best index of nerve regeneration. The fascial tubes became filled with a soft coagulum. Avis cylinders grew distally within the fascial tubes. Tubes remained patent for weeks during the growth of these nerve ends. Blood should be controlled for it interfered with good repair. He illustrated cell proliferation 2½ cm. proximal to divided end at different periods of time and emphasized the importance of keeping nerve ends in direct line and free from torsion that motor and sensory nerve ends may meet each other respectively.

Dr. A. A. LAW of Minneapolis, Minn., reviewed the use of decalcified bone, magnesium tubes, blood vessels, and egg-shell membranes and declared in Minnesota he had used fascia to best success.

Dr. J. GOLDEN of Chicago freshened the nerve ends before bringing them together. He asked whether it was necessary to oppose axon to axon or to leave them to find one another. He also said the length of defect in the nerve determined the quality of the repair. Had used muscles most satisfactorily to date.

Dr. MACKENZIE of Portland reported a case of tumor growing from the sheath of the sciatic nerve. It was diagnosed as sarcoma and its chief symptom was intense pain. He resected the sciatic from the lower border of the glutens maximus to its end, having the popliteal suspended. Marked trophic disturbances resulted, necessitating a second operation. He brought nerve filaments together from the remaining trunks and covered the anarlomoses by muscle.

Dr. RINKENBURGER of Los Angeles reported a case of ulnar paralysis functionally restored by anastomosis after two operative attempts.

Dr. LEWIS in summing up replied that he did not know whether the neurotrophism for sensory nerves corresponded with that of the motor neurones. He thought MacKenzie's case illustrated tubulization by muscle. He considered fascia, however, more accessible.

Election of Officers.—On nomination of the Executive Committee the following officers were elected: *Chairman*, Dr. E. W. Andrews of Chicago; *Vice-Chairman*, Dr. F. T. Murphy of St. Louis; *Secretary*, Dr. Samuel J. Mixter of Boston; *Delegate*, Dr. D. D. Lewis of Chicago; *Alternate*, Dr. W. D. Haggard of Nashville.

Selection of Operative Cases in Chronic Intestinal Stasis.—Dr. W. B. RUSS of San Antonio, Tex., read this paper. He gave a brief review of the literature to date—most of the cases got well under good management. Many were physically deformed, with unstable nervous systems and had evolutionary bands. In spite of these conditions they often, if left to themselves, lived to old age. Constipation was common and caused no bodily injury even though the bowels moved but once a week. The neuromuscular wall of the cumen and colon became atonic but gave no symptoms until it became infected. Surgical interference should be postponed as long as possible. He thought we were passing through a surgical fad similar to that characterized by kidney fixation and ovariectomy. He favored appendicostomy. He recognized as operative indications chronic appendicitis and back pressure with the ileum. Besides appendicostomy he plicated the dilated ceco colons and fixed them to the anterior wall.

Dr. J. N. JACKSON of Kansas City said there were two classes of workers that were detrimental to the progress of intestinal surgery, those with definite ideas based on small experience and those opposed to new ideas. He held that hopeful optimistic conservatism was necessary. The physiology of the colon was beginning to be appreciated although its surgery had been confined to mechanical indications. Many cures had been obtained by simple appendectomies.

Dr. R. C. COFFEY of Portland declared that he was the first to publish in the American Medical Association Journal a report of intestinal short circuiting. He later removed the same patient's colon. Later the patient presented himself, wishing to have the rectum removed and was finally said to have been cured by circumcision. He had concluded that operations involving opening the intestine were dangerous. He found peristalsis normal after short circuiting the normal gut and reversed in the case of the abnormal gut. He did not favor the Wilhis method. The best results were obtained by the removal of the ascending and half the transverse colon.

Dr. REA SMITH of Los Angeles said that there was no value in short circuiting the ileum for colonic constipation, but for stasis in the ileum the operation was useful. Most cases were properly medical. He doubted the wisdom of fixing the cecum without fixing the ileum too.

Dr. RINKENBURGER of Los Angeles had studied with Lane. Twenty young men, none of whom were over 22 years of age, showed the same intestinal positions by *x*-ray as Lane's operative cases had done.

Dr. R. T. MORRIS of New York thought that many of their ancestors short circuited. Intestinal cases were always complicated by other defects, ductless glands, ancestry and the like. Many were amenable to suggestion so that the picture was a composite one. Stiginata increase directly with cultural limitations of a race.

Dr. J. W. DRAPER of New York with his colleague, Dr. J. M. Lynch, had studied 13 cecocolons grossly and microscopically. In each there was a common mesentery to the terminal ileum and the colon; an evidence of non-fusion, and the ceca were of the herbivorous or pseudo herbivorous type. Microscopically, in three the normal mucosa was absent; in three there was beginning polyposis; in three Auerbach's plexus was absent:

in all the musculature was attenuated. Total colectomy should be avoided because of the importance of the intestine and caudad colon as an excretory organ for certain poisons.

Intestinal Adhesions. — Dr. W. B. BRINSMADE of Brooklyn read this paper. He mentioned trauma, infection and blood clot as three causes of adhesions. These might develop after operation, and might or might not be the cause of symptoms. Very slight adhesions might give severe symptoms; while very extensive adhesions might give no adhesions. There was no definite rule as to cause and effect. He had noted the free use of dry gauze in the European clinics in 1912. Operations upon dogs had confirmed his belief in the usefulness of rubber dam as an agent to prevent traumatism of the gut and subsequent adhesions. He had long since eliminated the contact of gauze, either wet or dry with the peritoneum. He had duplicated his clinical operations on dogs, using gauze in some and rubber dam in others. Less adhesions were found in those in which rubber dam alone had come in contact with the viscera. Six dogs were eviscirated at the surgical laboratory of the New York University and were similarly treated. In this series there were number of adhesions following the use of rubber dam had been used. W. H. Barber, at his suggestion, had operated on six dogs and found no difference in the number of adhesions following the use of rubber dam or gauze. In none of the animals were adhesions present excepting at the sites of the intra-abdominal wounds and on the posterior surface of the abdominal wound itself.

Dr. A. S. LOBINGER of Los Angeles considered anesthesia and subsequent intestinal narcosis a factor in adhesion formation, as well as chemical irritation due to antiseptics.

Dr. A. F. JONAS of Omaha said that the degree of adhesions depended upon the type of irritant and its intensity, whether bacterial or mechanical. Exposure to air; too many abdominal pads: particularly their changing—all these tended to increase adhesions. He advised the careful selection of the wound area, the use of visceral forceps, of moistened pads, the avoidance of frequent change of pads and the least possible handling of the intestine.

Dr. L. S. PILCHER of Brooklyn congratulated the section on the tone of the papers read before it. He considered Dr. Brinsmaid's paper very important. No more violence than just enough to accomplish the result should be used. Much depended upon individual judgment. He considered bacterial invasion a factor and the use of rubber dam a simple method. Laboratory experiments were not absolutely convincing. Sodium citrate should be considered.

Dr. J. W. DRAPER of New York said that he had assisted Dr. Barber in carrying on the laboratory experiments for Dr. Brinsmaid. These had more firmly fixed in his mind the importance of the essayist's contention that the utmost gentleness should be used in handling the viscera. The problem was, however, far from being solved because of the fundamental biological considerations to which Dr. Brinsmaid had also referred. These were in brief the ratio between fibrolytic and fibrogenetic forces which as yet could not be estimated and which differed greatly in all mammalian individuals.

Malignant Diseases of the Large Intestine.—Dr. H. B. DELATOUR of Brooklyn. Cancer was more frequent in sigmoid and cecum. Abderhalden reaction might be of value in determining diagnosis. The prognosis was good. Colostomy was often an essential, and the patient could be made much more comfortable than generally supposed by the use of a proper bag for for gatherng the feces.

Combined Abdominal and Sacral Operation for Carcinoma of Rectum.—Dr. D. F. JONES of Boston. By the time these cases reach the surgeon they are often hopeless and he urged a more careful study by the general practitioner and a more extensive operation than the Kraske by the surgeon. The combined operation in one thigh was too severe, as a rule, and should be done in two stages. A permanent colostomy, with excision of entire rectum, was the operation of choice. The essayist reported sixteen cases with three deaths.

Dr. M. F. PORTER of Fort Wayne, said that it often was hard to diagnose cancer of the intestine, even with the abdomen open. Good laboratory technique was very important as clinical aid.

Dr. C. B. DAVIS of Chicago said that Hartmann's prognosis after abdominal recurrence was 18 per cent. following sacral operation 68 per cent.

Dr. ALEXIS MCGLANNAN of Baltimore discussed the surgical pathology of carcinoma of the intestine and described two types: the cylindrical-celled, which matastasized late and the cuboidal celled which involved the adjacent organs early. In the latter case death was due to carcinoma; in the first, to obstruction.

Dr. L. J. HIRSCHMAN of Detroit emphasized importance of rectal examination in all suspected cases.

The Transverse Incision for Operation in Appendicitis.—Dr. A. E. ROCKEY of Portland had used the transverse incision for appendectomy since 1904. The incision is anatomically correct, being in the line of the nerve and muscle fibres and lines of the skin. After pus cases it was less likely to be followed by hernia.

Dr. FARR of Minneapolis preferred the oblique incision which avoided the nerves and cut the transverse fibers obliquely.

Dr. MOSCOWITZ of New York said that he used the Kammerer and MacBurney incisions for appendectomy and the transverse incision in the upper abdomen. It was most accessible for drainage and for suture and left but little scar.

Dr. CHRIS O'DAY of Portland requested that the transverse incision be tried, inasmuch as it could not be described.

Oration on Surgery: The Intestinal Tract.—Dr. SAMUEL J. MIXTER of Boston delivered this address. Intestinal malformations had been corrected; strictures and dilitations had been explored by the surgeon, thoracic esophagectomy remained the most difficult, and should be left for those experimenting upon it. The stomach was insulted in various ways and abused surgically. The excision of malignant disease and chronic ulcer of the stomach were accepted facts. In gall-bladder with a small stone of the strawberry type often caused some of the symptoms of ulcer. He had favored excission rather than drainage of the inflamed gall-bladder. Lymphoid tumors of the small gut occasionally required treatment. The appendix, when retrocecal, often passed unrecognized until rupture. It was often removed; although innocent, for disease in other parts of the body. The colon never lay in the lines and curves prescribed by the old anatomies. Fecal stasis was recognized as evil and to relieve it operations had been designed. Ptosis did not require operation. Neuroses and autointoxication required further study. The cause of adhesions was not known. The least traumatism; the use of wet gauze; the covering in of raw edges helped to prevent adhesions. Advance had been made in the treatment of intestinal stasis; the large intestine was more frequently the source of obstruction and required early operation. Create an artificial anus to save life. No one should attempt a serious operation without having served under a good master. The College of Surgeons represented a step in the right direction. One should operate first upon the lower mammals and should undertake gradual study in surgical research. Surgical judgment was more important than surgical skill, and the clumsy technician was less dangerous than the undisciplined operator.

Postoperative Roentgen Studies in Gastric and Intestinal Operations.—Dr. J. T. CASE of Battle Creek said studies should be functional rather than morphological and could be best made through the *x*-ray. Stomatized stomachs emptied rapidly and completely or rapidly and incompletely. The pyloric stoma was the site of election except for dilated, atomic stomachs. The contractile ring observed in the duodenum had also been observed in the jejunum aboral to the gastrojejunal anastomosis. Iliac stasis appeared not immediately but possibly within three years following ileo sigmoidostomy. Enemata might regurgitate into the ilea. In ceco-sigmoidostomy the current ascended both arms of the colon.

The Use of Inlay and Dowel Grafts in the Treatment of Fractures.—Dr. F. H. ALBEE of New York considered the indications for open operation and internal fixation in fresh and ununited fractures. He preserved the grafts in sterile vaseline 48 hours before using. He favored the elimination of all foreign substances—used kangaroo tendon for silver wire. He demonstrated his methods and instruments by lantern slides.

Dr. H. P. H. GALLOWAY of Winnipeg had performed fifty-six graft operations with good results. Foreign grafts might be inserted into infected areas and good union obtained.

The Suprarenal Gland in Shock.—Dr. J. F. CORBETT of

Minneapolis read this paper. He pointed out the epinephrin content of the normal gland and that of the gland in shock. He produced shock experimentally by traumatizing the intestines. He reviewed the work of Henderson, Meltzer, and Crile. Traumatic shock might depend upon epinephrin for its relief. He found the suprarenal cortext not affected in experimental shock. He considered shock a complex associated with adrenalin exhaustion and oligaemia. Trauma was an important causation factor.

Dr. J. E. MOORE of Minneapolis observed shock infrequently at the present time. To account for this he pointed out the more skilled anesthesias; the better psychological care of patients and the diminished sepsis. Why could shock not be prevented by the giving of adrenalin?

Dr. Corbett replied that it was his purpose to show how epinephrin became exhausted and how it might be preserved. When administered it did not prevent shock because the amount to be given was small and would have to be kept up for a long time and would injure the blood vessels.

Cystoscopic Methods in Ureteral Structure and Calculus.—Dr. BRANSFORD LEWIS of St. Louis demonstrated the direct and indirect methods of catheterizing the ureters. The intraneural ureter might be dilated or incised to secure relief from stone when the stone lay in reach. If above or cephalad to intraneural part a bougie might be passed to dilate below.

Dr. WILLIAM F. BRAASH of Rochester added that many stones existed in ureters without symptoms or indications of operation. It was best to dislodge them and allow them to pass. Peristalsis was strong enough to force out most stones of smaller size. The caudad ureter might be split without harm, as was shown by Draper and Braash in 1911.

Dr. LEWIS gave the mortality of 15 to 20 per cent for the operative removal of ureteral stones by abdominal section.

Roentgen-Ray Epitheliomas Curable by Radium—An Apparent Paradox.—Dr. ROBERT ABBE of New York said that *x*-ray irritation was occasionally followed remotely by cancers of varying severity. In stages of hyperkeratosis, epithelioma, or finally, squamous cell carcinoma. In the last stages it involved the lymphatics and was beyond favorable action by radium. The beta rays were the efficient force in the cure.

Experiences in Military Surgery.—Dr. W. E. DRENNAN of Birmingham, Ala., said the psychology of the soldier favored his convalescence. The treatment of wounds was free drainage. Cases of tetanus when operated upon often recurred. So the antitoxin should be given. The gas gangrene was best treated by multiple incisions.

Casualties of Modern Naval Warfare.—Dr. F. E. MCCULLOUGH of San Francisco said that laceration was common in all wounds and that infection was general. He pointed out that rifle wounds, particularly of the chest, were usually not serious. Iodine was not efficacious. He advised salicylic-boric acids to dust over the wound and a creolin base in ointment form. The nitrogen fumes of bursting mines proved very fatal.

SECTION ON THE PRACTICE OF MEDICINE.

Thursday, June 24—Third Day.

Specific Treatment of the Malignant Forms of Malaria.—Dr. C. C. BASS of New Orleans read this paper. He said that the malignant forms of malaria included those proving fatal; those which would die without proper treatment; and those cases in which the life of the patient was in danger. Practically all of these cases were due to infection by the estivoautumnal parasite. The only specific drug known was quinine and it was interesting to know the susceptibility of the estivoautumnal parasite to quinine. The life cycle of the parasite was 30 to 48 hours in the red blood cell. The parasite developed considerable size, reaching the full measure of the cell and was much more resistant to pressure than the tertian variety. Three-fourths of the life cycle of this parasite was spent in the capillaries, where instead of being elongated like the pliable red blood cell its resistance resulted in blocking of the capillaries. In this position it was inaccessible to quinine. Autopsies showed capillaries of important organs to have been obstructed. Anemia of the brain with subsequent coma was produced in this manner. These parasites could not be reached until they mingled in the blood stream. Many patients died of toxemic conditions in spite of large doses of quinine, even after the destruction of the parasite. Administration by mouth was useless in pernicious malaria. Introduction of bi-muriate of quinine subcutaneously or intramuscularly could be used, but it was irritating to some individuals. To obtain quick results, doses should be given intravenously, but not more than 30 grains in 24 hours, as larger doses were dangerous to the patient, and the patient died sometimes in spite of them. The enormous amount of foreign protein represented by the malaria parasite, as much as 600 c.c. to 6000 c.c. of blood, often caused a toxemia sufficient to kill the patient.

Dr. BREM of Los Angeles said he distinguished three groups clinically: (1) cases due to blocking of brain capillaries; (2) intense infection of the red blood cells, equal to .6 per cent of the cells, with accompanying hemoglobinuria; (3) the provisional group with hemoglobinuria, *i.e.* blackwater fever types. Quinine could not reach parasites lodged in the brain and the cerebral type did not recover. Quinine had been given intramuscularly, when impossible by mouth on account of vomiting. If given by mouth in the morning, one escaped the paroxysms of the disease which occurred usually in the afternoon, and the patient could retain quinine better, 30 grains thus given were better than 40 later in the day. Patients often showed intense toxemia at autopsy.

Dr. CHARLES S. WILLIAMSON of Chicago asked how long it was necessary to keep up treatment after apparent disappearance of the parasite from the blood. He had often been disappointed by the recurrence in cases he had supposed cured.

Dr. BASS replied that relapses were the exception rather than the rule. Relapses were usually reinfection. Malaria carriers were often present in the family of the patient and these persons were capable of reinfecting mosquitoes. Malaria parasites often disappeared from the blood in a few days. The condition leading to hemoglobinuria was the disruption of the parasites from the cell. Thus hemaglobinuria could be made worse by quinine. Quinine served only the purpose of killing the plasmodia.

Syphilis of the Stomach.—Dr. FRANK SMITHIES of Chicago made this presentation. He found dyspepsia in various forms often associated with a positive Wasserman. Exploratory laparotomy often demonstrated syphilis. In 6 years he had discovered 25 cases by serological tests among 7545 cases. The lesion might be part of systemic syphilis or a local manifestation. Changes in the stomach wall were relatively common, but gummata and scarring were not. The changes were in the form of round celled infiltration of the stomach wall with occasional enarteritis. Other types were miliary gummata; multiple inflammatory nodules, and gastric adhesions. Of the 26 cases, 15 were in females. The ages were from 20 to 56 years. It was difficult to get a history of primary sore, but history of chancres on the penis or mouth sore had been obtained in a few cases. The Wassermann and Noguchi tests had been positive. Eight cases had been treated. The serological tests furnished the basis for classification. This was not entirely conclusive as cicatricial or inflammatory conditions of tuberculosis were often influenced by salvarson. The cases were of three kinds: (1) persistant gastric derangement in persons previously well; (2) constant dyspepsia for years; (3) gastric upset, followed by years of apparent health, and then relapse. The *x*-ray did not always reveal pathagnomonic signs, but a characteristic sign was an abnormal outline with apparently normal peristalsis. This, with positive Wassermann, made the diagnosis certain. Treatment consisted of salvarsan and mercury injections, with iodines and free use of iron and arsenic. Diet and lavage were hopeful.

Dr. DUDLEY FULTON of Los Angeles said he had seen one case of true syphilis of the stomach, a male, 36 years of age, with apparently typical symptomatology of ulcer with tendency to hemorrhage. The Wassermann was four plus and the case cleared up under mixed treatment. Dr. Smithies' paper was the refinement of diagnosis and recognition should be more easy in the future than in the past. Operation was of doubtful value in cases with atypical signs, as proven by autopsy. The therapeutic test was not unquestionable proof of syphilis. Treatment instituted late was of little avail. The statement, too, of the patient as to syphilis should be corroborated by a positive Wassermann, by active evidences of the diseases and by *x*-ray. Then the therapeutic test was reliable. Cases were probably more frequent than generally recognized.

Dr. S. M. WHITE of Minneapolis said that this paper was important because syphilis of the stomach was frequently overlooked. The serological tests were of extreme importance in this connection. Syphilis of the heart was a similar question. It had to be considered.

Dr. EINHORN of New York said this was an important subject. He believed syphilis of the stomach was more frequent than generally admitted. There were varieties which give rise to tumor formation, simulating cancer of the stomach, with no free hydrochloric acid and with presence of lactic acid, occult blood and Boas Oppler bacilli. Surgery could not cure these patients. The Wassermann reaction was here of great assistance. Still, there were cases of syphilis of the stomach that gave a negative Wassermann. In one such case he treated the patient with iodide of mercury and the case recovered. In these cases antiluetic treatment did no harm to the patient and might do good.

Dr. GEORGE EUSTERMAN of Rochester, Minn., said he had had 21 proven cases of syphilis of the stomach. Ten had been exposed by surgery. These made recovery under antisyphilitic treatment. Eleven were non-operative cases and were diagnosed by the positive Wassermann and history of infection. The *x*-ray findings and evidence of gastric disturbance were important in these cases. Positive Wassermann reaction could not always be obtained. All his cases had definite symptomatology with marked reduction in enzymotic activity. Hemorrhage played a secondary rôle.

Dr. CHARLES E. SEARS of Portland, Ore., was interested in the therapeutic test as a diagnostic procedure. Undoubted cases with definitely proven lesions were few. It was safer to exclude cases diagnosed by the therapeutic test. In the majority of demonstrable cases he had found achylia present and also absence of pain; whether these symptoms were characteristic he did not know.

Dr. SMITHIES said that often there was absence of free hydrochloric acid in syphilitic lesions as in cancer, but in intermittent cases the Hcl. was about normal. He considered the positive Wassermann the surest diagnostic test. There was often hyperperistalsis and delayed emptying in these cases and a relatively low formaldehyde titration in the gastric extracts.

Gastric Cancer as a Sequel to Gastric Ulcer.—This paper was read by Dr. WILLIAM FITCH CHENEY of San Francisco. He called attention to three points: (1) gastric cancer occurred secondarily to chronic ulcer more frequently than was thought; (2) no definite methods existed for deciding when malignancy took place until advanced disease had occurred; (3) in consequence of this position, surgery should be advised with less delay. Unanimity of opinion was general as to the possibility of the first proposition. As to the frequency, surgeons reported variously percentages from 26 to 59 per cent and pathologists about 70 per cent of malignant changes. The German workers, however, considered that ulcer was often secondary to cancer, the ulcer occurring on the cancerous base. The differences were in the point of view, one set of observers judging from microscopical examination, the other from clinical history. Three types were established: (1) long repeated attacks; (2) the initial attack a few years previously, then sudden malignant development; (3) malignancy without previous symptoms *i.e.* patient did not consider symptoms important). The change to malignancy was impossible to detect. Loss of weight, anemia, no relief of pain by food, might occur without cancer, or might not be marked with cancer, nor were the gastric analyses entirely characteristic. Cases suitabale for operation were those in which food retention occurred or those which showed relapse. Resection or gastroenterostomy (in the later the duodenal contents regurgitated into the stomach) might be done; or, thirdly, combined resection and gastroenterostomy. Operation should be advised earlier without waiting till cancer has occurred.

Dr. FRANK SMITHIES of Chicago stated that the crux of the situation was the future history of the ulcer. Ulcer symptomatology was often simulated by gall-bladder or appendix lesions. The time factor was here an aid in differentiation. Where the history had been present eight years the ulcer had been proven by surgery or autopsy. Gastric ulcers might get well but, on the other hand, it rested with medical men to decide whether in chronic recurrent cases they should urge upon the patient an exploratory laparotomy with a 1 per cent mortality, or risk a later operation for gastric cancer with 100 per cent mortality.

Dr. MAX EINHORN of New York said he thought Dr. Cheney was very favorable to surgeons when he said 50 per cent of ulcers became cancerous. This did not tally with his experience. He did not consider chronicity and acidity constituted an ulcer. Of the severe cases a small number would become cancerous, probably one in 20. The minority did not improve. All ulcers could not be treated by this minority. Only cases of apparent mechanical obstruction should be treated by operation.

Dr. SPEIK of Los Angeles said that certain cases of mechanical obstruction were due to œdema or the pylorus and patients might improve. An amusing case illustrated this: A Jew, 65 years old, who had lost 70 pounds, with history of hyperacidity and frequent vomiting, came to the California Hospital for operation. He became frightened at the anesthetic and ran away. Dr. Speik took care of the man and with medical care and diet he became practically well and gained 60 pounds. Surgeons were often not competent and the mortality was as great in cases not suitable for operation as it was from cancer. Ulcer should be recognized early by medical men and given tyrannical treatment. Patients often dosed themselves with patent medicine and got temporary improvement. If these cases were taken early one should hear less of carcinoma of the stomach.

Dr. MACRAE of Philadelphia said he thought the difference in opinion was accounted for by the difference of material that came to surgical and medical clinics. Surgeons often thought hyperacidity meant ulcer and learned by operation that it was not so.

Dr. CHENEY said that there were three points: All ulcers were not ulcers; some got well. All cure was not cure; some relapsed. All surgery was not surgery; all surgeons were not competent. Medical men owed it to their patients to see that they had competent surgeons to care for them and also that surgery was not too long delayed.

Essential Factors in the Diagnosis of Duodenal and Gastric Ulcers.—Drs. CHRISTOPHER GRAHAM and GEORGE EUSTERMAN of Rochester, Minn., gave this paper which was a review of experimental and therapeutic advances in application of diagnosis of benign and chronic gastric ulcers, in 2400 cases, studied in the Mayo Clinic from 1900-1914. Eighty per cent of cases showed chronicity or remission of symptoms. Pyloric and duodenal ulcers without advanced complications showed periodic exacerbations, often in spring and fall. Factors influencing recurrence were—nervous and physical fatigue, infection, exposure, dietetic indiscretions, and intestinal disturbance. The average age was 12.5 years. Pain was the most constant symptom. Relation of food intake to pain was of diagnostic importance in 80 per cent of cases. Atypical cases were—perforating processes; chronic complicated types; severe cases where earlier symptoms were overlooked by patient; suggestive malignant types. Differentiation between gastric and duodenal ulcer was almost impossible; in 5 per cent of cases both lesions were present. The *x*-ray was valuable but not entirely reliable. The position, size and depth of the ulcer were important; if shallow, it might not be shown by *x*-ray. Pain to the left of the median line and the presence of occult or fresh blood were important diagnostic signs. The relation of pain to time of food intake was important. If the interval was long the ulcer was low; if pain was more prompt, the ulcer was higher. Hemorrhage was a safe diagnosis for ulcer in 95 per cent of cases; blood in stools in 25 per cent of cases. Appendix involvement in 2 per cent of cases showed blood in the stools.

Dr. J. N. HALL stated that more cases were due to appendix involvement than were clinically supposed. Presence of abdominal rigidity was an important sign. Its presence indicated organic lesion, not merely hyperacidity. There might be jaundice or biliary colic due to interference with the gall duct by the ulcer. Early surgery would save much mortality from cancer.

Dr. EINHORN said that cases with stagnation near the pylorus often came to surgeons and so they considered duodenal ulcer more frequent. Cases of gall-bladder trouble might be differentiated by examination of the bile through a tube. If it were cloudy, not clear, there was gall-bladder involvement.

Dr. J. A. LICHTY of Pittsburgh, said the differentiation between acute and chronic gastric and duodenal ulcers was important. This would decide which were medical and which surgical cases. One writer had stated that cases of gastric ulcer came to the internist about six years after onset, and to the surgeon ten

years after. It was foolish for surgeons and internists to quarrel over cases when so much damage had been done that neither could do the patient much good.

Concerning the End Results of Gall-Bladder and Duct Disease.—Dr. J. A. LICHTY of Pittsburgh read this paper, which emphasized the difficulty of making reliable and satisfactory diagnosis in gall-bladder and duct disease. Important points were the feeling among surgeons that next to appendix cases gall-bladder operations gave the best results, and the difference of opinion among physicians as to procedure, even when diagnosis was certain. In 600 cases 193 were operated upon and 407 not operated upon. Of the operated cases 25 died, a few less than non-operated. The fatal cases were usually common duct cases of long duration. These cases differed from appendix cases in that many refused operation. The appendix cases dared not refuse operation. The gall-bladder cases had intervals with no symptoms and often six years elapsed between diagnosis and operation, which explained the mortality in many cases. Gall-stone disease was frequently associated with pancreatic disease and 1 per cent glycosuria was found. Diabetic cases were 150 in 1400, thus the incidence was small. Indication for early operation was proven by the fatality of late common duct cases. The non-operated cases lead miserable lives and were frequently drug habitués.

Dr. J. N. HALL said that if people were educated for early gall-bladder operations, as they were for appendix operation, 30 per cent of cases which became later cancer of the gall bladder would be prevented.

Dr. MCGEARY of Los Angeles asked Dr. Lichty if he had found any particular etiological factor. The incidence of typhoid cases seemed small.

Dr. J. A. LICHTY said that he had been disappointed in his statistics regarding typhoid cases. He expected them to be high, but such was not the case. He believed the only marked factor was long standing digestive disturbance or hyperchlorhydria, leading to stone formation. Surprising results had been obtained from medical treatment and care.

Dr. EINHORN said he had found good results from glycerin medication two or three times a day.

Dr. LICHTY said he hoped that would not get out. The olive oil remedy, he thought, had occasioned loss of life by patients believing they could avoid operation. If they heard of glycerin they would be influenced in the same way.

Chronic Nephritis with Report of 250 Cases in Private Practice.—Drs. W. JARVIS BARLOW and R. L. CUNNINGHAM of Los Angeles read this paper. The report covered a period of eighteen years and was made entirely from a clinical standpoint. Four groups of cases were classified: (1) primary nephritis, 75; (2) cardiovascular nephritis, 82; (3) miscellaneous cases, 24; (4) nephritis secondary to tuberculosis, 69. Etiologically classified the groups were: (a) acute infections or alcoholism; (b) chronic endocarditis and arteriosclerosis; (c) chronic disease, infectious or otherwise; (d) pulmonary tuberculosis. In the group (d) the treatment depended upon the state of the tuberculosis. The true disease was associated with cardiovascular change; without this it was open to question. Many cases were due to toxemias and there was no real change in kidney tissue. With improvement in the infection albuminuria disappeared; if it persisted a true nephritis might later appear. The disease was most common in the sixth and seventh decade and appeared in indoor workers subject to mental or physical overstrain. Nephritis cases associated with joint pains occurred with *Streptococcus viridans* infections from the roots of the teeth. In cases with arterial hypertension the Wassermann was positive in five cases. Cases with retinal hemorrhages had usually a fatal prognosis. The urine analyses showed albumin in all cases. Granular casts were found more frequently than hyalin casts. Urea excretion varied with diet; a decrease was followed by retrogression and an increase by progress. A high specific gravity occurred in groups one and three. Treatment was climatic, hydrotherapeutic, dietetic, and by rest. A low elevation with equable temperature was most suitable to prolong life. A low proteid diet was an important factor, with red meat elimination. The bowels were kept active by fresh fruit and cereals. Helpful drugs were caffeine, strychnine and spartein. The conclusions were that under favorable conditions patients with chronic interstitial nephritis might enjoy good health for twenty-five years or more. Some cases were not true nephritis. These all terminated favorably.

Dr. ALEXANDER LAMBERT of New York stated that a primary kidney condition was different from kidney involvement in acute infections. The infectious cases could be improved more than those with cardiac lesions. The kidneys were primarily filters trying to filter out what was thrown in by the body. They could not handle metabolic cobblestones. The underlying metabolic changes lay somewhere between the ductless glands, the pancreas, and the liver. Exactly what the change was was not known. It had various names, gout, hyperthyroidism, pancreatitis, but the change was metabolic. Rest, diet, and equable temperature worked improvement, especially in the cardiovascular cases who were making a double struggle.

Dr. PHILIP KING BROWN of San Francisco said he had charted the histories of 6000 admissions to the Southern Pacific Hospital of cases with clinical symptoms of nephritis. He had tried to find out what the prognosis was for chronic interstitial nephritis with blood pressure above normal, in the working man. The patients were found to live on an average, five years, after diagnosis was made. Cases with syphilis were less amenable to treatment. In any case life could not be prolonged without complete change in labor and environment.

Dr. JOSEPH CIPES of Albuquerque, N. M., said that the fourth group of Dr. Brown, the tuberculous cases, did not receive as much consideration as the others, because when renal disease was found with tuberculosis, the doctor generally gave the patient up. Patients, however, often survived, to the surprise of the doctor. It was the duty of physicians therefore to find out whether the nephritis was parenchymatous, in which case the prognosis was often fatal, or interstitial, non-exudative cases, in which the patient had a fair chance for improvement.

Dr. BARLOW of Los Angeles said that if the patient could be tided over the trouble for five years, he had a chance to live for twenty-five, under proper supervision. Most of their cases were of the leisure class, in contrast to those of Dr. Brown, who were not able to have so much personal care. This accounted for the difference in the figures.

Standards of Urea Excretion.—Drs. THOMAS ADDIS and JUNSAI WATANABE of San Francisco read this paper. Dr. Addis stated that they had established a standard of urea excretion in young healthy adults in the hope that by comparison of the variations from this standard, an early diagnosis of chronic interstitial nephritis could be made. No test made the distinction between cardiorenal disease and arterial disease with cerebral hemorrhage. The phenolphthalein test to distinguish glomerular from tubular disease was not of value. It was unsatisfactory for the clinician. The earliest kidney lesions were functional and we did not know the normal functional variations. Experiments were therefore made for a six day period, with constant food and water intake, on a group of students and instructors to determine the urea levels in blood and urine. The 24-hour averages were taken and also 4-hourly specimens. The blood was collected the third and sixth day. Doses of 20 and 40 gm. urea were given at the commencement of each of the last three 24-hour periods and the concentration of urea in blood and urine compared, before and after giving urea. The concentration was found increased after the dose. The variation was slight in normal individuals, and possibly it would be found that in kidney disease the decrease in the urine was secondary to increase in the blood. "Ambard's constant" for blood and urine was tested. In normal cases a constant was found (0.06 to 0.08), but in cardiorenal cases, the results would be, according to Ambard, practically normal. The results depended upon the mathematical characteristics of the formula. Other investigators had corroborated this. In uremia the figures changed from 0.06 to 1.0 as Ambard stated, but this same conclusion could be reached by watching the urea in the blood. There seemed then to be no particular value in the formula, beyond pointing out a comparison of substances in blood and urine at the same time. Changes in the blood in early cases were slight; in later cases, very marked.

Botulism—An Experimental Study.—Dr. ERNEST C. DICKSON of San Francisco gave this study. He said that the causative factor had been supposed to be only spoiled meats. The toxin was produced by an anaerobic bacillus which caused a lesion in the Nissl granules and thrombosis at the base of the brain. The Darmstadt epidemic, in 1904, however, had been traced to bean salad, but the report stated that the beans had been

cooked with meat. Very little knowledge had been obtained from brains and cords of human beings in these cases, but the cord, pons, and medulla had been examined in experimental animals. In 1913 an epidemic occurred at Stanford University, the probable source being canned beans. Lesions in these cases were of the vessels at the base of the brain and meninges. Experiments were then made to culture the *Bacillus botulinus* in canned beans and also to determine whether thrombosis of the pia mater could be reproduced by toxins from this source. Canned beans were inoculated and allowed to stand from three to twelve months. The cultures were then made and animals were inoculated with fluid from the cans. The *Bacillus botulinus* was recovered in nearly all the cans. It also grew typically in a bean infusion. The bacillus had been supposed to grow in alkaline media, but these experiments gave results in a medium 3.2 acid to phenolphthalein. About 50 per cent of the animals died of botulism. This agreed with the mortality in human beings. At autopsy characteristic hyperemia of the abdominal vessels was found, with enlarged spleen, from which the bacillus was recovered. The meninges were congested and thrombosis at the vertex of the cerebellum was found. There was marked leucocytosis. These results showed the grave danger of badly canned vegetables. The ordinary methods of sterilization in home canning were not sufficient to kill the bacillus.

Dr. THOMAS MACCRAE of Philadelphia said that this was a valuable demonstration that many cases of so-called "ptomaine" poisoning were really due to acute bacterial infection.

Influence of Age and Sex on Hemoglobin—A Spectrophotometric Analysis of 919 Cases.—Dr. CHARLES SPENCER WILLIAMSON of Chicago presented this paper. He stated that the ordinary method of hemoglobin estimation, even in careful hands, was entirely inadequate for exact examination. There was no standard for hemoglobin which was applicable to all ages and both sexes, as a great variation existed. He had undertaken the compilation of a scale of hemoglobin standards by the spectrophotometric method in a large series of healthy, normal persons, or ages varying from fifteen minutes to 114 years. The class of persons above seventy-five years, however, had been taken as one group. The infants tested were breast-fed, robust babies. Hemoglobin was highest at birth, 100 per cent; after that it dropped rapidly, by steps, till at one year it was at a minimum. The drop was 25 per cent. At puberty, or about sixteen years, it had again risen to a stage, maintained for the rest of adult life, until fifty-five years, when it declined slightly toward old age. Sex differences were unimportant at birth. At puberty females were 9 per cent lower than males. This difference lasted during menstrual life and ten years after the menopause, when the differences again became unimportant in the declining years. This had an important bearing clinically. The differences of age and sex should be taken into consideration or one ran the risk of making a diagnosis of anemia in a perfectly normal individual because of a variation from an accepted standard, which was incorrect.

Dr. THOMAS ADDIS of Philadelphia asked what was the variation in a given group, say of sixty men, at a certain age.

Dr. C. WILLIAMSON replied that the variations at birth were trifling. In adult life there were variations of 10 or 12 per cent. In old age the uniformity was startling. By acquiring a standard we could determine the normal physiological variations. Experiments in raising the hemoglobin of normal individuals would be interesting. Institutional children showed on the whole a higher curve than children in private practice.

Prognosis in Heart Disease from the Point of View of Etiology.—Dr. W. H. WITT of Nashville, Tenn., read this presentation. He wished to urge a more scientific classification of disease of the heart. The question of prognosis in regard to valvular involvement, blood pressure, age, habits, etc., could be discussed in a general way. The value of appreciating the underlying cause was, however, undeniable. Myocardial insufficiency and endocarditis differed materially from tubercular and syphilitic lesions. Etiologically the classification was as follows: Syphilitic, nephritic, arteriosclerotic, infective, endocarditic, etc. In some cases the heart condition was overshadowed by other conditions, as in hyperthyroidism. In rheumatic infections there was often associated arthritis, tonsillitis, chorea, or other lesions. This group comprised 50 per cent of cardiac cases and the prognosis assumed great importance. Two important features were that in simple endocarditis the initial attack was followed by recovery; secondly, there would doubtless be a recurrence. The danger lay in the recurrence. The first attack was generally in childhood. In adults there was gradual decompensation. The reinfection of patients in these cases was a serious matter. Teeth or tonsils might play an important rôle and removal of foci of infection should be insisted upon. Poynton said that chronically infected tonsils must be removed. Syphilis of the heart had a tendency to attack the arteries and cause aortitis. True gummata were rare. Arrhythmias and precordial pains were characteristic in these cases. They cleared up with specific treatment. Serological examinations were to be insisted upon in such lesions. Syphilis was complicated by alcoholism. The haste of modern life was a factor in increase of heart disease. The patient would not heed warning and avoid physical and mental strain. No drug would help these overstrained hearts, and if the strain occurred under ordinary duties the prognosis was worse. Patients with cardiac disease who led sedentary lives might with advantage change to less heavy diet and more active mode of life. In anginic pains a slight precordial pain often had as severe a prognosis as marked pain. Such cases died suddenly. With high blood pressure the heart undertook more than it could do, and when associated with chronic interstitial nephritis the condition was more serious. When edema was present preventive measures should at once be undertaken.

Dr. CHARLES WILLIAMSON of Chicago remarked that Dr. Witt had said that the prognosis in heart disease depended upon etiological considerations, rather than upon anatomical. Dr. Williamson would add upon functional considerations also. He had done experiments to show the normal reaction of the heart to exercise. He had tried with cases with slight heart lesion and had given them exercise to the full extent of their power, 50 per cent of these had clean cut contractions about 1.5 cm. In ten or twelve cases of severely damaged hearts, with edema of feet, and enlarged liver, 50 per cent showed contraction. This showed that functional power was maintained in spite of the condition of the valve. A heart with slight mitral murmur, Dr. Williamson said, was in better shape than that with myocardial condition.

Dr. J. S. MCLESTER of Birmingham, Ala., said that the function of the heart, he thought, depended upon the extent of myocardial damage. Syphilis was a common factor, and in a large charity hospital 70 per cent of cases of myocardial insufficiency had been found to have a positive Wassermann. At autopsy many showed spirochetes in the myocardium. There was also a chronic parenchymatous nephritis in many cases. The kidney might be primarily the cause and not the heart.

Dr. WITHERSPOON of Nashville, Tenn., emphasized the fact that alveolar abscess was as important an infective factor as diseased tonsils. The dentist frequently reported normal gums where infection of the root of the tooth was present. *X*-rays must be taken and the infected teeth removed to prevent further infection and damage.

Dr. G. E. EBRIGHT of San Francisco stated that he thought a child might recover in the first attack of acute endocarditis, but the cases would become chronic in the adult. Cases in the child should not be overlooked. Complete rest for from three months to a year should be given in these cases until the myocardial irritability disappeared. This would prevent cardiac disease at 30 or 40 years.

Dr. WITT, in reply to Dr. McLester, said he thought that examination of the heart in untreated cases of syphilis, as in the negro, would prove instructive. In reply to Dr. Ebright he said that it was often impossible to give the necessary rest to children with endocarditis. Treatment should be directed to getting rid of the focus of the infection. In older people it was difficult to tell just where the focus of infection was. Teeth should no doubt be examined with great care by the *x*-ray method. Infected tonsils and teeth should be removed.

Hyperidrosis of the Palms.—H. G. Adamson reports a case of this condition in a girl aged 16 years in whom there was profuse and continuous sweating of the palms and palmar surface of the fingers of both hands. From time to time large vesicles formed about the fingers and burst, leaving sore places.—*Proceedings of the Royal Society of Medicine.*

STATE BOARD EXAMINATION QUESTIONS.

STATE BOARD OF MEDICAL EXAMINERS OF GEORGIA.

Atlanta, October, 1914.

(*Continued from Vol.* 87, *p.* 1050.)

PATHOLOGY.

1. Name and describe briefly the forms of infiltration.
2. Discuss the practical diagnostic value of the leucocyte count, both total and differential in acute appendicitis.
3. Name the different forms of sarcoma, and give the microscopic appearance of the round cell type.
4. Discuss anaphylaxis.
5. Give the pathology of pellagra.
6. Give morbid anatomy both macroscopically and microscopically of chronic interstitial nephritis.
7. Give morbid anatomy of atrophic cirrhosis of the liver.
8. Give the lesions that occur in the intestines in dysentery.
9. Give the etiology and morbid anatomy of acute simple endocarditis.
10. What conditions favor cerebral hemorrhage?

ANSWERS.

PATHOLOGY.

1. "*Fatty infiltration* is the deposit of fat within the cell or intercellular tissues. May be general or local. It may occur in cells that normally contain no fat, or else appear in excess in cells that do contain it. The fat contained within the cells is made up of neutral palmitin, olein, and stearin.

"*Glycogenic infiltration* is a deposit of glycogen within the cells. It is found normally in small amount throughout the body except in the mammary glands and central nervous system. It is greatest in amount in the cells of the liver, in voluntary muscles, and in the kidneys; is also present normally in the blood, both in the plasma and in the cells, particularly the polymorphonuclear leucocytes. It is also commonly found in malignant tumors of the mesodermic origin (sarcomata). The origin of the glycogen is not clear; it is a carbohydrate, but seems to be derived from proteid and carbohydrate substances. Glycogen is most frequently found in the condition known as diabetes.

"*Serous* or *edematous infiltration* is a condition of dropsy of the cells. All kinds of cells may be involved, but it is most common in the epithelial. It is an absorption of an excess of plasma by the cells.

"*Pigmentary infiltration* is the deposit of pigment within the tissues. According to their origin, pigments may be divided into four classes: (1) Those derived from outside of the body; (2) those formed from hemoglobin and its derivatives, the hematogenous pigments; (3) the hepatogenous or biliary pigments; (4) metabolic pigment; that resulting from cellular activity within the body is known as melanin.

"*Calcareous infiltration* or *calcification* refers to the deposit of earthy salts within the tissues. It occurs in consequence of a deficiency of oxygen and an excess of carbon dioxide in the tissue juices, which causes a deposit of the carbonates and phosphates of magnesium and calcium. Oxalates are also generally present. This process occurs only in those tissues that are either completely destroyed or else undergoing degeneration as a result of imperfect nutrition."—(McConnell's *Manual of Pathology.*)

2. "Catarrhal appendicitis is accompanied by a mild degree of leucocytosis, rarely above 12,000. An increasing leucocytosis, from 15,000 upward, generally indicates a severe infection. In some cases of severe catarrhal appendicitis one may find a count of 25,000 to 30,000. If the count remains stationary, it is indicative of a walling off. If the leucocyte count decreases gradually in a mild attack, it signifies improvement. If it decreases suddenly after a severe attack, it signifies either gangrene, perforation with beginning peritonitis, or the rupture of an abscess into the general peritoneal cavity. The majority of cases in which perforation or gangrene occurs early, and causes peritonitis, have a low leucocyte count, owing to the lack of resistance on the part of the organism and the overwhelming of the system by the toxins.

Gibson believes that with a moderate rise of the total leucocytosis there should be, in favorable cases, a moderate rise of the polynuclear cells only, showing that the infection is localized and absorption is limited. On the other hand, if there is only a moderate leucocytosis with a notable increase in the polynuclear cells, it indicates almost unquestionably that there is either a severer form of lesion or less resistance to absorption, or that both conditions exist."—(Eisendrath's *Surgical Diagnosis.*)

3. FORMS OF SARCOMA. (1) *Round-celled:* Embryonic or immature connective tissue. Blood-vessels without walls, or thin-walled, ramifying among the cells. Small or large round cells, embedded in a small amount of granular or homogeneous intercellular substance. (2) *Spindle-celled:* Cells varying much in size, spindle-shaped, with long, fine tapering extremities, separated by very little intercellular substance. Often have a fibrous appearance (Recurrent Fibroid). (3) *Giant-celled (Myeloid)*: Masses of protoplasm containing two or more nuclei—up to 20 or 50—with a varying amount of round and spindle cells. (4) *Alveolar:* Alveolar space filled with sarcoma cells; the trabeculæ composed of spindle-cells. (5) *Melanotic:* Sarcomata of various kinds in which brownish or black pigment becomes deposited as amorphous granules in the cells as well as the connective tissue and blood-vessel walls of the tumor.—(*Cyclopedia of Medicine and Surgery.*)

4. *Anaphylaxis* is a condition of supersensitization induced by the injection of a serum. It is the opposite of prophylaxis, and in place of rendering the person injected immune the serum has made him particularly susceptible. It has been followed in some instances by alarming symptoms, such as: Heart failure, collapse, convulsions, coma.

5. "The exact cause of pellagra is unknown. . . . The anatomical changes are not constant. In the spinal cord degeneration of the posterior and lateral tracts occur. The intestinal lesions consist in some instances of ulcerations, but are inconstant. The frequent occurrence of amebæ has been noted. The other lesions are those commonly found in all chronic wasting diseases."—(French's *Practice of Medicine.*)

6. "*Chronic interstitial nephritis* may sometimes be secondary to chronic parenchymatous nephritis, connective-tissue overgrowth having become marked, and resulting in contraction of the kidney. Usually, however, it is a primary affection, and is known as renal cirrhosis, red granular, granular, or contracted kidney. In the diffuse form the kidney is reduced in size, it may be to one-third the normal or less, is hard and markedly granular. The capsule is adherent, leaving a rough surface on removal. Small cysts are often present on the surface filled with urine or colloid. The kidney is hard on section, the cortex much reduced in width, and cysts may be scattered through its substance. The color is reddish with whitish mottling, and in gouty cases there may be whitish striæ, due to deposits of urate of soda. *Microscopically*, the lesions are principally seen in the cortex; at first patches of cellular infiltration appear, then the intertubular connective tissue becomes increased and fibrous, with destruction of glomeruli and the corresponding tubules. The glomerular epithelium becomes swollen and desquamates, Bowman's capsules may be much thickened by concentrically arranged layers of nucleated fibrous tissue, and the Malpighian bodies in places may be converted into nodules of fibrous tissue, in others into cysts. The corresponding tubules undergo atrophy with disintegration of their epithelium; here and there multiplication, with convolution of the tubules, may be present, suggesting an adenomatous formation. There is everywhere an increase of the stroma, in the cortex and pyramids, between the tubules, and around the glomeruli and vessels, with pronounced round-celled infiltration or well-formed fibrous tissue, in which calcification may occur. The vessel walls are thickened, chiefly owing to an endarteritis. Lardaceous infiltration may accompany the interstitial nephritis."—(Hewlett's *Pathology.*)

7. *Atrophic cirrhosis of the liver.* "In a well-marked case the liver is smaller than normal and presents both marked induration and shrinking, the new connective tissue being disposed in large bands which run in various directions and by their contraction divide the organ into many irregular lobes. When these latter are small they project above the surface and resemble nail heads, hence the name "hob-nail" liver, sometimes applied.

Owing to the arrangement of the fibrous bands the condition is sometimes called "multilobular," since many acini at a time are grouped and constricted by it. The liver tissue, sharply circumscribed, presents a yellow color if fatty, and with admixture of bile pigment may be darker. The capsule may be thickened or adherent to the diaphragm, the gall-bladder presents no constant appearance except that it is often empty. Adhesions form between the abdominal walls and contents and tend to relieve the portal stasis for a time.

"*Microscopically* the formation of connective tissue may be traced in all its stages in the line of the portal subdivisions, in the youngest places appearing as a focus of round cells about the sheath of the veins with later development of spindle cells. These foci blend and the fibrous tissue becomes poor in cells and firmer, coincident with contraction. This causes compression of the portal capillaries and at the same time there is often an obliterating endophlebitis; the result is to offer an obstacle to the entrance of the portal blood, with increasing stasis throughout the origins of the system. This explains many of the clinical symptoms, the ascites, gastric and intestinal catarrh and hemorrhage, piles, and distention of superficial abdominal veins (caput medusæ), to which latter effect ascitic distention adds. Jaundice, however, appears later if at all and the spleen is not swollen till toward the end."—(Thayer's *Pathology.*)

8. "In *acute bacillary dysentery* the principal changes in the intestinal mucous membrane are: (1) Intense hyperemia, the mucosa being swollen, corrugated, and here and there hemorrhagic. (2) Necrosis, and fibrinous exudate, with formation of a pseudo-membrane. (3) Ulceration, at first on the summit of the folds, but extending both deeply and laterally.

"In *chronic bacillary dysentery* the mucosa is thickened and granular, and the whole gut is thickened. There are chronic ulcers with thickened edges, and areas of scar tissue. Consequently there are partial strictures of the bowel, which is dilated above. A typical dysenteric ulcer therefore has the following characters: (1) Site; on the ridges of the large intestine. (2) Edges; irregular and thickened. (3) Base; may be formed of any of the coats. (4) Tendency to contraction on healing. The so-called 'diphtheritic dysentery' is a form in which necrosis is very extensive and the development of pseudo membrane pronounced. In advanced cases the whole mucosa may form 'a black, rotten, friable, charred mass' (Rokitansky).

"In *amœbic dysentery* the lesions are chiefly seated in the large intestine. They present—(*a*) small gelatinous swellings of the mucosa, with partial ulceration; (*b*) necrosis and sloughing of the underlying tissues. The ulcers of amebic dysentery thus have undermined edges. The amebæ are found in the ulcerating mucosa, but more abundantly in the tissues beyond the ulcerated area (submucous or muscular coat), where they set up edema and necrosis. Later, along with the ulcers, cicatrices, leading sometimes to partial stricture, may be found." (Wheeler and Jack's *Handbook of Medicine.*)

9. ACUTE SIMPLE ENDOCARDITIS. *Causes:*—"It is usually secondary to some other affection, particularly acute articular rheumatism (especially in young people), chorea, pleurisy, pneumonia, pericarditis, Bright's disease, and the infectious fevers such as scarlatina, influenza, and diphtheria. Gonorrhea is an occasional cause. Cachectic states such as accompany tuberculosis and cancer are predisposing causes. It may be secondary to chronic endocarditis.

Pathology.—"Acute simple endocarditis may be prenatal as well as postnatal. In the former class of cases, the right side of the heart is usually involved, while in those instances observed after birth the disease is most often limited to the left side. While the disease may attack the entire lining membrane of the heart it is especially marked at the valvular portions of the endocardium. The earliest change is that of hyperemia of the membrane, rendering it red and swollen. As the inflammatory exudate is thrown out the surface of the valves become roughened and warty excrescences are formed. These verrucose formations are to be found on the auricular surface of the mitral valve and on the ventricular surface of the aortic valve at the line of contact of their leaflets, usually from 1 to 2 mm. from their free margin. These vegetations are produced by a proliferation of the cells of the adventitia and of the external connective tissue; fibrin from the blood is deposited on the formations, thus serving to increase their size. The excrescences are friable and may be easily detached or broken off and carried in the blood stream as emboli, to various parts of the body, particularly the left side of the brain, the kidneys, and the spleen. If retained in position fibrous tissue is eventually formed; the valves become thickened and contracted producing chronic endocarditis. The leaflets may then become the seats of various infiltrations."—(Hughes's *Practice of Medicine.*)

10. *Conditions favoring cerebral hemorrhage:*—Age, syphilis, gout, alcoholism, rheumatism, uricacidemia, arterial sclerosis, increased arterial tension, Bright's disease, overexertion.

THE TONSILS AND THE STRUGGLE FOR EXISTENCE.

By R. G. ECCLES, M.D.,

BROOKLYN, NEW YORK.

In peculiar contrast to other bodily organs the tonsil possesses the unique distinction of having given rise to the most flatly contradictory of opinions as to whether it is of great advantage or great disadvantage to its possessor. Why is this so? How have such irreconcilable ideas arisen? The problem here raised is of very much more than mere controversial importance, for, as we shall presently perceive, upon its solution may hang the future comfort, freedom from protracted illness, and the lengthening of the lives of great multitudes of people. Our textbooks on physiology strongly reflect the obscurity with which we are confronted whenever we attempt to gain from them any light upon the subject of the tonsil's function. If summoned to act as witnesses in court and expecting to be asked to state to judge or jury the use, to man, of his tonsils, what reply could we make? Diligent search for knowledge upon this in any of our libraries would show a remarkable dearth of information therein. Some books would be found to ignore the subject completely that we might, naturally, expect would tell us all we would require to know about it. Others would supply hazy statements of no value. Still others would flatly acknowledge our ignorance upon the question. "Physiologists," says Dr. Faulkner, "know nothing of faucial tonsils. Their textbooks do not mention them. * * * There is no accord even in the definition of a normal tonsil."[1] He had evidently been trying to gather some information on the subject from our authorities and failed. Some of us find ourselves about where Prof. Austin Flint confessed being during a college examination. He is reported as having asked a student under examination to tell him the function of the tonsils. "To swell and suppurate in quinsy," came the reply. "What, then, is the function of the spleen?" continued the professor. "Why, to enlarge in malarial fever," answered the student. "That will do," the professor is said to have replied, "you have passed a perfect examination, for you know as much about the subject as I do."[2]

At that time a growing belief in the doctrine of organic evolution was stimulating a more than usual study of comparative anatomy and this, naturally, gave promise of being able to enlighten us upon these dark subjects. It was found that reptiles, birds, and mammals are furnished with tonsils, thyroid glands, thymus glands, etc., but that on descending to the fishes the respiratory gills take their places. In the mammalian pharynx pouches opening out from the side into the cervical region indicate where the gill clefts are in the anatomy of the fish. The Eustachian tube and middle-ear, the tonsils, the thymus gland, and the thyroid gland in us appear to mark the old relationships. "Structurally," says Gaskell, "the thymus, parathyroids, and the epithelial cell-nests are remarkably similar, so that the evidence appears to point to the conclusion that, in the neighborhood of the gill-slits, segmentally arranged organs of a lymphatic character are situated, which give origin to the thymus, parathyroids, tonsils, etc."[3] In considering the embryology of the subject Mackenzie states that the tonsil "does not develop as a lymphatic gland from a plexus of existing lymph vessels in the mesothelium, but as an ingrowth of the endothelium from the second bronchial pouch, and, therefore, in origin must be classed with the thymus and the thyroid, the former originating from the third and the latter from the fourth, while the parathyroid takes its origin from the third and fourth branching pouches, all by inbudding of the endothelial lining of the primitive pharynx."[4] If tonsils have developed from ancient gill-glands, are they readaptations of such glands performing a new but kindred function to that which they performed in fish, or must we consider them as more like coccyx, appendix, or ear-moving muscles, mere degenerating and now functionless organs? For nearly half a century, immediately following the publication of the Origin of Species, the latter view predominated. It did not seem to occur to any one at that time that inasmuch as swim-bladders had been transmuted into lungs, fins into legs and feet, and the forelegs of quadrupeds into arms and hands of men that the glandular structures associated with gills might become something useful to mammals. There was nothing in the history of tonsils to indicate that they were, like the appendix, atrophying. On the contrary, the evidence, such as it was, seemed to indicate that they were becoming relatively somewhat larger in the most highly advanced organisms. The belief in their degeneration kept growing stronger, however, until it was deemed a mark of erudition for one to be able to refer to them as vestiges of the past. Inasmuch as no particular function could be attributed to them it was thought best to assume that they had no function. This refusal to hold the mind in suspended judgment, until some substantial facts could be secured, was, in great part, due to a faulty conception of heredity. They supposed that the form and structure of every organism resulted from some sort of polarity of the body as a whole, whereas, now, we are coming to see that these are most likely due to tropisms residing within the individual cells. Cell stimulates cell, producing a result that is due to symbiotic relationships between them. A disturbance of these relationships,

unless very great, is not likely to be serious for the simple reason that there are recessive qualities fitting them, when called forth, to alter the final result and produce another different harmonic form. Heredity may be dual or triple for any given organism, but the stimulus must occur early enough in the development to produce the different results. These new results have been interpreted as acquired characters and thus has arisen a belief in the inheritance of characters which were already inherited, under the supposition that they were hereditarily new. The gill-glands, that became the tonsils and thyroids of the higher organisms, had but to readjust their cell responses to the altered stimuli of the changing environment. Natural selection had, long before, given them recessive qualities which the altered stimuli made dominant. The phagocyte-harboring tonsils are, probably, the phagocyte-harboring glands of the gills and the thyroidine-producing thyroids are, very likely, iodine-secreting glands of the same organs. The old functions were only slightly altered to suit the new conditions and even the alterations were, perhaps, latent characters.

Had the facts, on which these suppositions are based, been known when the majority of biologists were beginning to realize the truth of evolution there would have been far greater hesitancy in condemning the tonsils as useless vestiges than there was. Having been impeached at the bar of the then scientific judgment there very soon were discovered other reasons for their utter condemnation from that viewpoint. Among the earliest of those who made a bitter attack upon them was Sir William W. Gull, a well-known and much respected English physician, and Fellow of the Royal Society. When addressing the Clinical Society of London, in 1872, he said: "In our bodies we men have many organs which are of little or no use to us, and are only relics of a former state of being. What, for instance, is the comparative anatomy of the tonsils? Were I to make a man, I do not think I would put tonsils in him. Yet these, and such like organs, in accordance with the general law, are more prone to disease than are the others which are of real use in the system." This fact of their being more prone to disease than other organs would, at that time, have proven a staggering argument against any one who should have dared to come to their defense for, as we shall presently see, it was only too true. He closed his remarks with the statement that, "The surgeons ought to be indebted to me for hints toward the extermination of superfluous organs—a grand prospect for the surgeons of the future."[5] The publication of these remarks, by Professor Youmans, in the first number, of the first volume, of the *Popular Science Monthly*, made them carry a tremendous weight in the moulding of medical and surgical opinion in the United States. Gull's prophecy that this was "a grand prospect for the surgeons of the future" turned out to be appallingly true if recent bacteriological and pathological research work can be relied upon.

As soon as medical attention became centered upon what the tonsils seemed to be doing for us the tide of condemnation became irresistible. The unusual number of diseases—both chronic and acute—that, somehow, appeared to be correlated with tonsillar inflammations multiplied, under investigation, to an alarming degree. Vast epidemics, as well as great numbers of sporadic cases, of our worst acute infections were found to act as if the contents of Pandora's box had been emptied into our bodies through these organs. It was not long until numerous papers were written advocating their merciless extermination. Ballinger's book on Diseases of the Nose, Throat, and Ear tells us that "It is being more and more recognized that the complete enucleation of the tonsil with its investing capsule is the most satisfactory method of dealing with diseased tonsils."[6] Dr. L. M. Hurd tells us that "The tonsils may be clinically divided into three classes: (*a*) The large round glands that hang almost free in the throat; (*b*) Those which partly protrude beyond the tonsillar pillars and are partly imbedded between, and (*c*) Those which do not protrude at all and are more or less covered over by the pillars. This latter is the so-called submerged tonsil. The first class is the least harmful and probably most often removed, for they are easily recognized, and as easily removed. The second and third classes cause the more general trouble and are less often recognized, because the general idea is that the protruding and large tonsil is the offender. * * * The opinion of many good observers is that the lymphoid tissue of the throat is the point of entrance for measles, scarlet fever, and other exanthemata; acute articular rheumatism, pero-, myo-, and endocarditis, arthritis, adenitis, osteomyelitis, strepto- and staphylococcus infections, and possibly chorea, neuritis, certain forms of nephritis, pleurisy, iritis, phlebitis, Hodgkin's disease, and appendicitis."[7] Surely no more appropriate spot could have been chosen for degenerating vestigeal organs to appear than that occupied by the tonsils, had malevolent "purpose" aimed at the most refined form of torturing our race. This list of maladies tells of the perfection of the exposure to infection. The ophthalmologist to the Conemaugh Valley Memorial Hospital, Pennsylvania, tells us that "When a tonsil once becomes diseased it is apt to continue its malign influence, causing an extension of inflammation which affects the ears and nasal passages or gives rise to various ills in remote parts of the body. * * * The condition of acute tonsillitis is well known to all of us, but I feel positive that its importance is often underestimated. In addition to the usual symptoms it has given rise to otitis media, edema of the glottis, acute endocarditis, rheumatic fever, pneumonia, and gangrene of the lung. I have personally treated one case where septicemia and hemorrhagic nephritis resulted. * * * The pharyngeal tonsil histologically presents a structure simulating that of its faucal neighbor. It possesses crypts and may be the seat of acute inflammation which is often undetected. In its hypertrophied form we know it as 'adenoids' or 'adenoid growths.' As such it impedes nasal breathing and associated or alone causes impaired speech, chronic rhinitis, cough, mouth breathing, middle-ear disorders, permanent facial deformity, and a profound evil influence on the mentality and general health. Mouth breathing is an evil of grave consequences. The face becomes narrow, a vacant expression is present, the teeth are poorly arranged, the palate is highly arched, intruding upon the nares, and the dust-laden, unwarmed air is drawn directly into the lungs. The outcome of this is a narrow-chested, weak-lunged individual whose entire respiratory tract is weakened, making him quite susceptible to any disease affecting these parts, and no small number of tuberculosis cases can point to a similar history and condition."[8]

If the non-resisting qualities of the tonsils, due to their being atrophied or vestigeal organs, is the cause of so many deaths and so much suffering there would appear to be plenty of good reasons for their extermination. But, if this is the correct explanation it is a wonder that Natural Selection has not rid our bodies of them long ago. European physicians have likewise taken notice of their apparent malignant influence. When Sir Felix Simon, Physician Extraordinary to his Majesty the King of England, was visiting the United States, in 1904, during his lecture at the Long Island College Hospital, he dwelt earnestly on this subject, treating particularly of numerous, very malignant forms of pneumonia, nephritis, edema, and general septicemia which had frequently come under his observation. He declared that these unusually severe and highly fatal cases he had found were associated with tonsillar inflammations. He declared that "Diphtheria in the majority of all cases shows itself first in the tonsils. * * * Most of the acute septic processes, of which I speak, commence in the form of the apparently ordinary tonsilitis." "Surely," the reader now thinks, "it will be difficult to explain away such a mass of incriminating evidence and to defend the tonsils as organs of any particular value to their possessors." It has been my purpose to try and make the case against them as strong as possible. But still another serious accusation that is brought against them needs to be emphasized so as to do justice to the side of the opposition. Vast epidemics of streptococcic and diplococcic infections have been traced to the tonsils as the chief places of first attack. These have been reported from many regions, but the cases of greatest interest occurred in Christiania, Boston, Chicago, Baltimore, Minneapolis, and a number of English cities. The numbers of people infected ran up into the thousands in several of the cities named. In the Chicago epidemic there were several thousands attacked. In the Boston epidemic Cambridge alone claimed to have had about one thousand sufferers. In and around there the onset of the attacks simulated diphtheria but produced by far its highest mortality among the aged and infirm. Dr. E. A. Darling reported that of 527 patients whose sex was recorded, there were 160 males and 367 females, or 30 per cent. of the former to 70 per cent. of the latter. One-fourth of all the cases had complications such as abscesses in the throat, axilla, legs, lumbar and gluteal regions. Some 38 cases had arthritis, 11 pneumonia, of whom 8 died; 5 laryngitis, 7 acute endocarditis, 6 acute nephritis, and 2 phlebitis. The source of the infection was traced to one of the best kept and most up-to-date dairies in America. So perfect was its management and equipment that Professor Rosenau took his students from the Harvard Medical School there to teach them the advantages of "certified" over ordinary milk. Prof. W. T. Sedgwick, our American authority on sanitation, commenting upon the situation said: "Milk is incriminated as a carrier of disease. It can carry scarlet fever. The community has already suffered severely from these, and now a new form of iniquity is placed on milk. For the first time, also, a milk producer has employed a skilled man to make a thorough examination and bidden him tell the whole truth. That truth you have had tonight. Like Dr. Rosenau, I have long had and am continuing to have the Deerfoot milk in my own home. The greatest lesson of all is the utter inadequacy of milk inspection."[10] The lesson seems to be that inspection and certification are impotent when undiscovered carriers are around scattering viable germs. Dr. Hirschberg stated, in relation to the Baltimore epidemic, that the most striking clinical picture was, "The sharp onset, with the invasion always in the throat, general adenitis, great virulence, fulminate type of death in forty-eight hours in the lethad cases, impossibility of proving milk, water or food responsible in the spread of the epidemic, and the constant presence of the pneumococcus as a possible causative organism. In all of my cultures, obtained from abscesses, glands, ear discharges, infected tonsils, and other secretions * * * an encapsulated diplococcus was isolated. This organism was also obtained by me in pure cultures from an epidemic fatal to white rats that occurred in one of the laboratories of the Johns Hopkins University." Of forty-two cases, he states that one had enlarged cervical glands, 10 had enlarged submaxillary glands, 10 had remittent fever for two weeks, 1 had appendicitis, 1 died of peritonitis, 1 died of septicemia, 3 had arthritis of different joints, 8 had pharyngeal injection with systemic infection but no tonsillar involvment, 6 had bronchitis, 4 otitis media, 1 a mastoid abscess, 1 meningitis, 1 peritonsillar abscess.[11] Dr. L. P. Hamburger, in reporting the same epidemic, claims that it was traced to the milk supply as a whole but not to one particular dairy. He also claims that it was transferrable from patient to patient, from the ailing to the well.[12] While there were cases that show no tonsillar involvement this does not mean that an examination of the tonsillar flora would not have shown the presence within them of the offending bacterium.

With so startling a mass of facts arrayed against the tonsils, singling them out as the chief agents through which diseases may enter the body, and with what was long taken for a sound scientific theory pronouncing them inherently dangerous, because of their supposed degenerative proclivities, can we wonder that the tide of public opinion should have turned strongly against their retention when they happened to become inflamed in any degree? Inasmuch as a majority of children are said to have inflamed tonsils at some time in their growing years there was plenty of incentive toward a general "massacre" of these organs. The sentiment, indeed, became so strong that Dr. Mackenzie declared that "A leading laryngologist in one of our largest cities came to me with the humiliating confession that, although holding hostile views against its performance, he had been forced to do a tosillectomy in every case in order to satisfy the popular craze and to save his practice from destruction." One distinguished surgeon of large practice whose experience had convinced him that complete removal of the tonsils was decidedly injurious to many, if not all patients, told the same gentleman that it was "his deliberate opinion that of all the surgical insanities within his recollection this onslaught on the tonsils was the worst."[13] Even the general public seem to have an acute attack of tonsilomania if the story is true that one lady came to her physician and requested him to remove the tonsils of her little daughter "because she sometimes wets the bed." This is all, of course, the result of the medical profession having given these organs a bad name. Such is the force of public opinion that if a saint came to

be secretly reviled and had no opportunity to defend himself he would have to suffer unredressed. But for the general belief that no persisting organ can be as wholly bad as these were claimed to be, there would have been no one left to do them justice or to defend them against their accusers. Deaths due to hemorrhage in tonsillectomy, and impaired phonetic qualities in the voices of those that had been subject to this operation, soon came to give strength to the opposition and to the general principle upon which it was based. Then came a reversal in our views regarding the nature of inflammation that has been working in favor of the conservative treatment of tonsils ever since.

Whatever may be the chief reason for the existence and perpetuation of these glands one function that should not be overlooked is the phonetic. Owing to their size, position, structure and form they must constitute no inconsiderable fraction of the total vocal apparatus in man. Dr. R. B. Faulkner, of Pittsburg, has laid particular emphasis on this point, in his volume of 400 pages on The Tonsils and The Voice in Science, Surgery, Speech, and Song. That this is not their sole function, nor even their chief function, is at least suggested by the fact that those in the carnivora much more nearly resemble those of man than do those of the herbivora. In the devouring of the carcasses of other animals there is far more danger of infection from mammalia-invading parasites than there is in living upon grass, fruit, or grain. Man's meat-eating habits have always placed him in this same danger. On the theory which the writer advocates, that all proteins have been selected because of their power of resisting certain kinds of parasites, the meat itself is a danger, through its anaphylactic qualities, just as bacteria and protozoa are. The anaphylactic danger from living parasites and dead meat may in some way enable us to account for this resemblance in tonsils. If we can discover that they have some sort of fixed relationship to invading parasites and to meat-eating we will, probably, be on the way to the discovery of their most important use. In 1882 Metchnikoff made some researches on the lower forms of animals, at Messina, Sicily, that seem to have a bearing upon this subject. He then gave the first steps of the proof that the destruction of parasites in these forms is a part of the ordinary process of digestion. He says: "The *Daphniæ*, those small crustacea so numerous and so frequent in fresh water, furnished me with a favorable medium in which to study a real struggle which takes place between their leucocytes and the spores of a vegetable parasite belonging to the group of Blastomcetes. In many cases the ameboid cells guarantee the integrity of the animal by devouring a large number of these spores and transforming them into an inert detritus. In other cases, on the contrary, the fungi get the upper hand in the struggle; they succeed in germinating and in overcoming the resistance of the leucocytes by reproducing themselves rapidly and by killing these cells with their poisons."[14] In such a case as this there is no essential difference between immunity against infection and the ordinary digestion of the host. If we carefully study these two processes—digestion and immunity—all the way up from the protozoa to man we will find ourselves unable to tell where the one ends and the other begins. The two parallel each other while showing a tendency to become separate functions but the separation is never—not even in man—complete. When an amœba devours bacteria they constitute its normal food. When the bacteria acquire the power of thwarting the digesting ability of the amœbæ a condition of disease results. If we ascend the scale of life to the sponges we will discover the continuance of these two processes side by side. In the sponges many cells are grouped into a single organism and we find that "Food substances in the form of minute organisms, which have penetrated the pores of the sponge are seized by the ciliated or ameboid cells lining those spaces, and are then killed and digested."[15] When organisms enter the pores of the sponges that they are unable to digest, disease occurs, for the latter turn the tables upon the sponge cells and digest them. If we next investigate the Polyps we discover that their digestive sac or gut is "lined by digestive cells which have the same ameboid character as phagocytes, and actually digest to a large extent by swallowing or taking into their individual protoplasm raw particles of food. Such particles are inclosed in a temporary cavity, or vacuole, into which the cell protoplasm secretes digestive ferment and other chemical agents. Now there is no doubt that such digestive vacuoles may burst and so pour out into the polyp's stomach a digestive juice which will act on food particles outside the substance of the cells, and thus by the substitution of this process of outpouring of the secretion for that of ingestion of food particles into the cell we get the usual form of digestion by juices secreted into a digestive cavity."[16] Here we see that stomach digestion began as a form of phagocytosis and that the two processes are fundamentally identical.

We all know that the leucocytes of our blood, and of the blood of all vertebrates, still continue to seize and digest pathogenic organisms just as do the amœbæ of ponds and the cells of sponges. At the dawn of life the struggle for existence could only have been a struggle of monocellular with monocellular organisms. Each sought to rob the other of its living substance by acting thereon with its digestive fluids. At no time from that day to this can it be conceived that this sort of thing has ceased. To-day, as it was millions of years ago, monocellular organisms attack our free-floating leucocytes, the monocellular organisms of our blood, and endeavor to digest them while our leucocytes retaliate by trying to digest the invaders. "If you fail to digest me I will digest you," is the law of every living thing to-day as it was in primitive times when the earth contained only protistan forms. Enzymes are now, just as they were at the dawn of life, the chief instruments of warfare. The struggle between Metazoa, with tooth and claw, has been superimposed upon this more fundamental and more far-reaching and important part of that destruction out of which fitness continuously survives. Our skins and intestines constantly carry potential enemies of this microscopic kind and these refrain from digesting our cells only because the latter are able to hold them at bay by the use of resisting substances. When we get chilled or hungry, heated, wounded or bruised, wearied or faint, thus getting out of proper adjustment with our environments, the armed neutrality between our cells and our minute foes is destroyed and we suffer. When the environment varies in ways that make readjustment difficult then these enemies rise in open conflict and start disease. The lessening of

the resisting power of a host gives the advantage to its load of microscopic fauna and flora, converting them from potential into actual enemies. This we are constantly made cognizant of when we see tissues invaded by *Bacillus coli*, streptococci, or staphylococci. In the inflammations which supervene we have struggles in which the cells automatically tend to maintain the integrity of their structures and their proper places within the organisms, and to dislodge and destroy the invaders, while the latter, with a similar blind pertinacity, tend to destroy the cells and convert them into microbe pabulum. Burnet tells us that "Phagocytosis is summed up by intracellular digestion,"[17] but it is equally true that microbic pathogenicity is summed up by microbe digestion. Ehrlich likewise gives us to understand that the complements and amboceptors of immune sera are digesting agents.[18] To the biological chemist any other explanation is improbable. He is compelled to reconcile the matter with his knowledge of the fact that carbohydrates, fats, chitins, proteins, and other tissue substances, are all, so far as he has been able to discover, hydrosynthetic products. Their decomposition, by reversal of the synthesizing process, can be only through hydrolytic cleavages. The digesting enzymes of sera are probably, as declared by Metchnikoff, products of the phagocytes so that all bacteriolysins are subject to rational explanation when we look upon them as digesting substances similar to or like those of the pancreas. Pfeiffer's reaction is perfectly simple when viewed from this position. Its specificity is easily explainable when we take into consideration the differences in the material structures of different species of bacteria or of other microbes. They differ in their membranes, in their envelopes, in their proteins, in their nuclear material, in their linin, etc. Every such difference means a corresponding difference in the composition of the digesting fluids that will be capable of dissolving them. According to Ehrlich the amboceptor, and not the thermolabile complement, carries the specificity. This would mean that each particular substance requires a different kinase to start the reaction which the enzyme facilitates. In bacteriolysis the first thing that has to be digested, in a number of known cases, is the waxy envelopes in which they imbed themselves. When the leucocytes are unable to do this the bacteria can multiply in defiance of them. After the removal of this envelope other amboceptors and, probably, other complements, are required to digest the semi-permeable membrane that envelops the protoplasm. This gone and still other parts of the bacterium require still other enzymes and amboceptors.

The presence in the serum of these different digestive substances, matching the chemical compositions of the microbes, constitute what we know as bacteriolysins. Moor and Hewlett have shown how these act. They say: "If a mixture of microbes and serum be injected into the peritoneal cavity of a guinea-pig, and after half an hour a microscopical preparation of the peritoneal exudate be made, it will be found that the microbes are in all stages of dissolution—that is to say, the serum causes the solution of the microbes, and so destroys them. This is termed bacteriolysis, and the phenomenon is known as Pfeiffer's reaction, after its discoverer. * * * Pfeiffer's reaction is a very specific one, and is largely made use of to determine the nature—*i.e.* the species—of a microorganism. If a vibrio isolated from a water be suspected to be the cholera germ, some of the culture, together with some anticholera serum, is injected into the peritoneal cavity of a guinea-pig. If bacteriolysis occurs, the vibrio is cholera; if not, it is some other species. Metchnikoff subsequently showed that the reaction would occur *in vitro* (in a glass flask) if to the mixture of microbes and serum some of the fresh peritoneal exudate of a normal guinea-pig was added. Bordet afterward found that the reaction occurred *in vitro* in the mixture of microbes and immune serum alone, provided that the serum was perfectly fresh."[19] The *specific* serums used in these tests are procured from animals that have previously been treated to repeated doses of the specific microbes concerned in the reaction. The animals into which the microbes are injected gradually produce a serum that is able to dissolve the particular kind of microbe with which this inoculation occured. To secure sera for other microbes the same process must be gone through for each. The body-cells require time to produce these results whether the microbes are injected artificially or enter during an infection. The leucocytes, or other cells concerned in bringing about these results have to be, what we may call, "trained" into the power of producing such sera. Microbes having the ability to produce waxy coverings that defy the body's enzymes, and protect them from lysis, become, if they are able to multiply, exceedingly dangerous. The cells are unable to dissolve or injure them. A microbe that is able, through this trick of covering itself with indigestible wax, to defy the digesting powers of both leucocytes and sera, is not chemotactic to phagocytes and should it be able to produce, while in this condition, its cytotoxins, *i.e.* cell digesting substances, we would expect it to be negatively chemotactic. The phagocytes would move away from it. As soon as the cells are able to produce substances that can digest the capsules these would act as opsonins producing positive chemotaxis. This, at least, is the simplest and most probable explanation of what happens in these cases. It may be that reducing substances derived from the amino acids may aid in the poisoning of the cells on one hand and of the microbes on the other, but it seems evident that the chief work of destruction, accomplished by both cell and microbe, is due to the hydrolytic cleavages which they are able to produce. When Hektoen tells us that "It does not necessarily follow that phagocytosis of bacteria is always synonymous with their destruction," he has but stated a truism, if the phagocytes only act by digesting and in some cases the bacteria are indigestible.[20] It is a well-known fact of biology that the digestibility of different species and genera varies very greatly, particularly in their external coverings. The enzymes that digest hair cannot digest wool with the same facility. Those that digest the hide of one animal may find it difficult to digest the hide of another. Those that digest the kernel of a nut would find it difficult, if not impossible, to digest the shell. Those capable of digesting the shell of a filbert might not be able to digest the shell of a walnut, a hickory, or a Brazil nut. Those that could digest the shell might not be able to dispose of the outside husk or pericarp. Those able to hydrolyze the outer coverings of beans and peas might fail with the inner coverings. It is thus seen that there is great diversity in the chemical natures of outside coverings with great

specificity. Look where we will, throughout the living world, and this specific character of the outer coverings is everywhere discernible. The fact that bacteria and protozoa differ among their respective species in this same way is not at all surprising. Bacteriolysis and the digestion of food being fundamentally identical we should expect bacteria to behave, under digestion, much as our food would behave if we swallowed it intact—unchewed or intact. Unbroken nuts, unhusked corn, unskinned birds and fish, etc. would require specific treatment in being digested. The enzymes for digesting hair, wool, feathers, scales, and other such specific coverings would not be able to manage hide, and those that could dispose of the kernel of a nut could not dissolve the shell. Under such conditions each particular article consumed at a meal would require a different digestive fluid. In the lysis of bacteria each species has to be dealt with in a different manner, and time is an element in the readjustments. In order to obtain this time our bodies have pursued the very ancient plan, seen as far down as in the sponges, that of having their motile cells meet the bacteria or protozoa at the very earliest moment of their invasion. By attacking them thus early they gain enough time to be able to adjust their digesting powers to the particular invader. Metchnikoff, in his book on Immunity, tells us that "Some years ago Stöhr demonstrated that the wall of the intestine and especially the tonsils and other lymphoid organs are traversed by an enormous number of leucocytes which execute a kind of migration toward the cavities containing microorganisms. This continual and normal condition is often termed Stöhr's phenomenon. It is evident that we have here a process of phagocytic defense in which the leucocytes, disseminated through the digestive canal, give chase to the microorganisms that are nearest to the living portions of this organ. When we remove a particle of mucus from the surface of the tonsils of a person in good health we always find that it contains leucocytes, especially microphages, filled with microorganisms of all kinds."[21] Adami confirms what Metchinkoff has declared by telling us that "If we examine a scraping or swab from the surface of the pharynx or nose, we find that this contains fairly abundant leucocytes. In other words, leucocytes are constantly passing out between the epitheliel cells to gain the surface. Many of these, properly stained, show within them bacteria and their remains. They are acting as scavengers and cleansers. It seems probable that the majority, having performed their functions, undergo dissolution or are swept away by currents of saliva. But some, at least, find their way between the lining cells into the subjacent tissues. This can be well determined if one takes, as did Riffer, the rabbit's tonsils, kill the animal, remove and immediately harden and prepare the tonsil—staining sections for microorganisms. The tonsils are essentially lymph nodules, lying immediately beneath the surface epithelium. Such sections show, besides the lymphocytes forming the lymph nodes, two other orders of cells, the one polynuclear —some of which contain bacteria—the other, larger cells of endothelial type and origin (Metchnikoff's macrophages), of which some contain polynuclear leucocytes and their remains. * * * * It is wrong, therefore, to imagine, as it is too often taught, that the hinderance to the entrance of bacteria into the tissues is, under all circumstances, complete in the healthy individual. *A certain number of microbes is always gaining admission*—nay, is being actively introduced by the cells of the organism. But, *under such circumstances they do not cause infection. In health they tend to be destroyed very soon after their reception.* The evidence that this is the case is now overwhelming. It is true of the lower respiratory tract. Careful study of the peribronchial glands shows the same presence of intracellular bacteria, although not so abundantly as in the tonsils. It is true also of the intestines. * * * That such leucocytes as have escaped into the lumen of the gut and have returned can and do pass into the blood stream, has been demonstrated with admirable precision by Prof. A. B. Macallum of Toronto. * * * And, lastly, not to dwell on the convincing results of Nocard, Ravenal, and Behring, upon the passage of tubercle bacilli and other organisms into the lymph of the thoracic duct of dogs and other animals when fed more especially with fatty foods. Dr. W. W. Ford, in our laboratory at the Royal Victoria Hospital, has demonstrated most conclusively that immediately after death organs like the liver and kidneys of dogs, cats, rabbits, and guinea-pigs are not sterile, but contain some few bacteria, which are capable under favorable conditions of still growing. * * * These observations, then, prove conclusively that *bacteria are constantly entering the organism.*"[22] Such discoveries greatly unsettled our old beliefs concerning the sanctuarized conditions of blood, lymph and viscera. The doctrine taught a generation ago that disease germs could gain no access to the circulation except through traumatisms is now completely discredited by the cold, hard facts revealed to us by the microscope. Leucocytic diapedeses have a wider range than was supposed—a range that includes the gland walls within the alimentary canal, in the absence of inflammation. The leucocytes have here a function to perform that was not dreamt of by our thinkers of the last century. In their ingress and egress migrations they carry bacteria to and from the blood in ways that seem puzzling.

Dr. Barth, in a lecture on the Physiology of the Tonsils, given at a meeting of the Verein für Innere Medicin, of Berlin, in 1907, showed that it had been experimentally proven that bacteria and colored substances, such as carmine, when injected into the circulation reappeared in the tonsils, and were discharged by them into the palatal cavity.[23] It has long been known that in morphine poisoning a large part of the morphine can be recovered from the stomach when it has been given by hypodermic injection. Dr. A. F. Hess, after injecting *Bacillus prodigiosus* directly into the blood of rabbits and dogs found that these organisms were "excreted from the blood, not only by way of the liver through the bile, and the kidneys through the urine, but also to a less extent, directly through the intestinal wall. This was found to take place in one hour when one platinum loop of culture medium was inoculated."[24] Campbell and others have shown that in syphilis cases *Treponema pallidum* germs are carried by the leucocytes from the seat of lesion to the tonsils with such constancy that their presence in carefully secured serum smears from these organs is easily demonstrated in a large proportion of cases. Indeed, so constantly has he found them in primary, secondary, and tertiary cases that he has been able to use this method as a means of diagnosis. He tells us that when the tonsils present no

superficial lesion, but are enlarged and hyperemic they are invariably present. When they present an absolutely normal appearance he has found the Treponema "in most cases of secondary syphilis." In no case where syphilis was absent did he ever find them.[25] To know that the acid of the gastric juice has the power of destroying most, or all, bacteria that develop in alkaline or neutral media, and that the duodenal contents can sterilize those able to run the gauntlet of the stomach, is to perceive great usefulness in this carrying of pothogenic microbes that are able to resist phagocytic digestion, to the tonsils, to be emptied into the palatal cavity. Dr. P. H. Hiss, starred as a bacteriologist of the highest standard, in American Men of Science, adds a new and far from improbable light to this subject. He says that "It is not, in this connection, to my mind, a far-fetched idea to suppose that phagocytic cells may depend naturally on other cells and bacteria as a part of their regular food supply. The polymorphonuclear leucocytes may thus depend to some extent on the ever-entering bacteria and their remains; for, as we know, bacteria are constantly entering along the regular channels of absorption."[26] As has already been shown, there has been no cessation, during the entire course of phylogeny, to this sort of leucocytic activity and that at its beginning it was purely an act of food securing. There is absolutely no evidence that at any time during this exceedingly long period bacteria have ceased to act as food for these cells. Why should they when they contain the very same amino acids as the cells contain and as the cells use from other foods?

From the standpoint of both leucocyte and microbe immunity is nothing more than getting the upper hand of prey in the hunt for pabulum. Nor does this apply to the leucocytes alone among the body cells. There are many good reasons for believing that every cell in the body is able at times to act as a phagocyte. Dr. Washbourn says that "The endothelial cells of the vascular system are phagocytes capable of englobing bacteria which have entered the circulation. * * * Werigo showed that anthrax bacilli after injection into the circulation of rabbits at once disappeared from the blood, being englobed by the endothial cells of the blood-vessels; and this has been shown to be true for other bacteria. The endothelial cells of the blood-vessels of pigeons infected with swine septicemia are found to be crammed with bacilli; and similar phagocytic functions have been found in other infections."[27] This division of labor in the disposing of pathogenic microorganisms enables the body to cope with a far greater number of them, at any single invasion, than it otherwise could attend to. But, inasmuch as we have seen that *all immune reactions against microbes must be more or less specific*, for the reasons already presented, there is required to be the most complete harmony of action between the cells as a whole during an engagement with an army of rapidly multiplying invaders in order to compass their destruction or expulsion. For one lot of cells to be secreting enzymes adapted to the destruction of *Bacillus coli* when the invader may be the anthrax bacillus would be working at cross purposes. For some of the cells to have themselves in readiness to digest protein only, others carbohydrate only, and still others waxy substance or fat only, when all are needed to face the anthrax invaders would be to be found in a condition of utter unpreparedness. They would be at the mercy of the enemy, and particularly so if that enemy came fresh from the invasion of a host of the same species. The enemy would be fully prepared—positively virulent—while the cells would be incapable of making even reasonable resistance. It has been again and again experimentally proven that it takes time for the cells to prepare themselves for such emergencies.

The first production by any organism of any given specific serum is never the work of a day. To fabricate proper antibodies to match newly introduced antigens requires time. The so-called "period of incubation" is now believed to cover the number of days needed for these preparations as well as for the multiplication, up to the invasion strength, of the enemy. Few, if any, pathogenic microbes are ever able to get into the circulation in sufficient numbers to cause septicemia in less time than is covered by this "period." Few, are able to overwhelm the circulation with their "toxins" in less time than this, when they are, as organisms, unable to themselves reach the blood stream. Whatever may happen to be the portal of entrance they must reach a place of sufficient safety for themselves so as to permit of speedy multiplication. They must, in the meantime, adjust their powers of resistance to the lysins of the cells, otherwise their rapid multiplication is impossible. While they are multiplying, and while as they multiply they increase the amount of their toxins, the cells, too, are busy acquiring the power of digesting the invaders—of dissolving off protecting envelopes, and of matching and rendering non-injurious the cytotoxins. If an army of microparasites came upon the cells at once, in sufficient numbers and with sufficient digesting power to destroy great numbers of the cells a defense would be impossible; invasion would mean the death of the host every time. Here then we gain a clear conception of the tremendous importance to the body of the migrations of leucocytes into the digestive tract. It is a taking captive of the advance guards of the invading army, an experimental discovery of the secret of the way to dissolve their armor, a sensible system of early preparedness. Stöhr's phenomenon is thus seen to be of life and death importance to every living species of animal, particularly when young, and the tonsils are the first open doors for them through which to perform their most efficient work of salvation. They lie near to the entrance of the digestive tract and their structure is such that it could not well be improved upon for the most facile way of conducting such a campaign. It shows the utmost preparedness for facilitating the transportation of leucocytic troops and for their return with prisoners to the detention camps where they can be utilized to the best advantage of the body.

The British Encyclopedia tells us that the tonsil "is very vascular, deriving its blood from five neighboring arteries."[28] This the reader cannot help seeing is just such a condition as would, by the aid of leucocytic diapedeses, enable the freest possible communication, in many directions, with the circulation through the body, so as with the utmost possible speed to disseminate the inoculating material. Speed in mobilization and in obtaining war supplies is among the most important of martial advantages. The tonsils are built in exactly the way that supplies to the body this very advantage. They occupy the very place, too, that helps in this particular. The soldiers of the body

do, actually use them, for this very purpose. Every known fact about them fits exactly as evidence of this explanation. That others have partly anticipated me in this view of the matter is made evident on learning from the *Journal of the American Medical Association* that "Orandorf considers that the tonsil has for its function the early establishment of immunity to bacterial toxins. Its location is the most suitable point for the certain collection of specimens of every kind of microorganism entering the oronasal cavity. When the bacteria have been in the crypts long enough to elaborate a sufficient vaccine, which is transported by the lymph current through the system, an immunity not associated with a toxemia has been induced for that form of bacterium. This organism is then annihilated by bacteriological substances brought by the returning lymph current and is removed from the system."[29] The bacteriological substances here referred to are, from our viewpoint, the hydrolyzing enzymes and their cooperating chemical aids. The bacteria are literally, and not figuratively, digested, as much so as they would be in the alimentary canal. Instead of being removed from the system it seems more likely, from a knowledge of their chemistry and chemical changes, that they serve, in great part, as pabulum for the body. The existence of the crypts as catch-alls for bacteria adds materially to the fitness of the tonsils for the performance of the function herein outlined. The elaboration of the vaccine, however, occurs wherever cells are acting as phagocytes and digesting the parasites. The crypts can do but a trifling part of this. It is the work of cells in all parts of the body. When rapidly accomplished there is sure to appear the symptoms known as inflammation. This, as we see, is itself a defensive reaction. When the tonsillar invasion is overwhelming, so that a negative chemotaxis occurs, we have, as pointed out by Dr. R. C. Brown, in the MEDICAL RECORD, a systemic infection without a tonsillitis.[6] In this condition the swift diffusion, without local injury, increases the chances for survival by its greatly diluting the virulent toxins and bringing the individual microbes face to face with myriads of phagocyting tissue cells as well as leucocytes. This, of course, results in a general septicemia—a terrible fate for the host—but, all things considered, the best result possible and the least of two evils. To have made the other choice of an utterly hopeless local inflammation, with uncheckable gangrene and necrosis of tissues, would certainly have been no improvement. In negative chemotaxis the best thing that can be done is to dilute, and thus reduce the overwhelming virulence. These results are precisely such as we have reason to expect if biological adaptations are the results of Natural Selection. They always fall considerably short of ideal perfection. They are always of such a character as to be subject to a good deal of improvement. On any other theory of their production they stand as an everlasting evidence of mismanagement on the part of their "purposeful" producer.

The modern doctrine of inflammation with which this view of tonsillar function corresponds is well stated by Adami, in Allbutt and Rolleston's System of Medicine, in which he says: "We regard the irritant as capable of causing cell- and tissue-destruction, and so long as the irritant is in action so long may this destruction continue. But inflammation itself we regard as the series and sum of the reactive processes set up in the tissues, and then bringing about, not destruction, but the very reverse. Taking as our definition, that inflammation is the response or reaction to injury, we are inevitably led to see that this response results in counteracting, or more exactly in tending to counteract, the deleterious effects of the irritant; the inflammatory process tends toward repair. It may not result in repair, for, as we have pointed out in several instances, too often the reaction is either inadequate or excessive. * * * Studying the various factors involved, it is forced more and more upon us that each tends in one definite direction, and the sum of the processes is reparative."[31] In explanation of this reparative trend the same author states that "In the course of evolution those individuals survived who, by chance, let us say, happened to manifest this reaction on the part of their vessels in response to stimuli of a certain order, whereas those who did not were more unfavorably placed and so succumbed; that they conveyed the same power to their descendants who also possessed this advantage over individuals incapable of affording the reaction; then we can conceive the development of a race possessing a mechanism for countering a given stimulus by a given reaction, a race in which provision is made, or gained, for dealing with a given order of events; then it will be seen that what primarily is accidental becomes secondarily purposeful, through the survival of the fittest and the inheritance of defensive acquirements."[32] This modern view of inflammation puts a new phase on the entire subject of pathology. In the case of tonsils it compels us to make a radical overturning in the old viewpoint. Without having been at all conscious of the incongruity of our position we have all along been inclined to reason about them much as Mark Twain, in one of his funniest moods, undertook to reason about going to bed. A friend was telling him of his terror when on fast trains and in steamships because of the many people that met death through accidents to the trains and ships. Mark replied that he had been making a study of the official statistics of death rates and found out that many more people died in bed than anywhere else and this had made him terribly afraid of venturing into a bed. Our surgeons have been studying the death rates from tonsil infections and discovered that more people suffer and die through these than through any other source of infection; *ergo*, tonsils are dangerous things and must be gotten rid of.

What if these organs do become inflamed with greater frequency than most others? What if through them have passed more, and more malignant, infections than through any others? If our cells are, ordinarily, unprepared to meet, successfully, the invasions of pathogenic microbes, and if these cells require from a week to two weeks to make the necessary preparation for the repelling of the majority of attacks from such microbes, and again, if the tonsils constitute one necessary part in the mechanism of the preparedness, how can we justify an operation which forever after it is performed defeats the very results for which such tonsils were selected as fitnesses in the struggle for existence? When these organs are laden with the debris of dead leucocytes and dead bacteria, when they are swollen to such an extent as to check respiration, or when, in any way, their damaged condition seriously handicaps any other organ in the performance of some important function, no

one should object to a tonsillotomy. Even in this, however, we should not lose sight of the fact that we are only choosing the lesser of two evils. The microbes, and not the cells of the tonsils, are the offenders. To sacrifice a single tonsil cell that can be safely saved is to sacrifice a small fraction of regenerative material—is to do that much damage to the patient. By all means get rid of the microbes and in doing so the less tissue cells removed the better. Nor is it necessary, in order to get rid of the microbes that are scattered through the gland that every part of the gland must be removed. A certain number of the invaders can be destroyed by the cells after the overwhelmingness of their numbers has been reduced. When the inflammation is not excessive, when the leucocytes are diligently at work destroying the parasites, and when regeneration and restoration of the damaged tissue are slowly going on, why should we seek to increase the trouble at the risk of the future comfort and life of the sufferer? That the theory here presented explains numerous facts which have not before been explained or correlated, is evident. If it is true, as already seems probable, then whenever a tonsil is wholly removed its owner must face future infections with a reduced ability to overcome the same. If it is a child, then it must die from the scarlet fever which attacks it a month, a year, or several years later, though the virulence of the attack be no more than would have caused a slight indisposition had the tonsils remained. And this is equally true for every kind of infection that is likely to attack it during life. Otherwise mild diseases, even though they may not kill, are rendered much more intense, injure more organs as complications, and leave the patient a chronic invalid where he might have passed the ordeal of attack with but trifling damage. If the patient is an adult, an invasion of *Diplococcus pneumoniæ*, that would have ended as a trifling affair had his tonsils been intact, gains sufficient virulence through lack of bodily preparedness to terminate his life. In view of such grave possibilities why should we not be glad to assume the position taken by Dr. J. W. Jarvey, when he said: "I doubt if there is a surgeon who will not admit having seen many excellent and permanent results following tonsillotomy; yet, many plead for tonsillectomy as a routine procedure. Do they practise what they preach? If they do they are wrong, for they admit the frequent efficiency of the simpler measure; and, if they don't they are wrong again, for they are misleading those whom they should teach aright."[33] Until the surgeon who advocates tonsillectomy can show some other meaning for Stöhr's phenomenon than that here presented, until he can show why the tonsils have differentiated in adaptation to the evident requirements of many different kinds of mammals, instead of atrophying as his theory of them requires, until he can show why their circulation is so great while that of the os coccyx, appendix, and other vestigial organs, has shrunken into an almost negligible amount, he is assuming a terrible responsibility. He is blindly risking the future career of his patients on a gamble which he knows is one of great uncertainty, even should he have the hardihood to deny the premises and conclusions here presented. How could he possibly know that a death that occurred years after his operation may not have been due to that operation, until he has found some other meaning for Stöhr's phenomenon than that here given? Besides this tonsillectomy is far from being free from more than the ordinary dangers of other operations of like size. The risks from hemorrhage must be more than usual when fatal bleeding may occur from either of the dorsales linguæ and from either the ascending or descending palatine. The carotid, too, is endangered.[34] Why jeopardize the patient's life when the only thing that can be reasonably charged against the supposedly offending tonsils is that of being where contending armies meet often to test the patient's fitness to survive the struggle?

Poor Belgium is at present performing the tonsil function for war-cursed Europe. We can see with what tragic results to her people she is compelled to take this part. If, because of the serious state of inflammation in Belgium, and because that over her soil invading armies passed to produce a similar febrile condition in France, what would we think of the intelligence of the French people should they blame the Belgians for their troubles and earnestly advocate the destruction of the whole people of Belgium in reprisal? Belgium, too, suffered in a somewhat similar way during the battle of Waterloo. What if the English, the Germans, the French, and the Austrians should unite in bringing this up against the Belgians because, forsooth, that battle was correlated with a severe febrile condition through all of Europe? With all the muddled logic that the present war has produced nothing quite so muddled has been proposed as the massacre of the entire Belgian people in order to avoid future repetitions of such diseased conditions. Yet this is the kind of logic by which tonsils have been sacrificed making it impossible for them ever to regenerate or take any part in the future weal of the body. It is exactly as if we held that the future peace and comfort of Europe depended upon Belgium being converted into everlasting marshes and deserts. The war will leave a heritage of ruin, irritation, poverty, and pain that will rack the sensibilities of other peoples for years to come, but no one is likely to be foolish enough to condemn the poor Belgians for this trouble. When the armies have been removed and industry reestablished there will be regeneration to heal the injuries and restore the usefulness to mankind of these poor people. It is exactly thus with the tonsils unless new diseases appear. Conservative treatment of any organ, like the conservative treatment of a crushed people, is the best treatment. If the lungs or heart offend we know better than to advocate their extermination. The functions they perform are too evident for anyone to suggest their complete removal. Where other functions are less immediately vital it is safe to assume that they exist and require as careful treatment even though death may not be imminent. It is the surgeon's duty at all times to choose the lesser of two evils and it is also his duty to be sure which of the two is the lesser.

FLUOROSCOPIC BRONCHOSCOPY.*

(SUPPLEMENTAL REPORT.)

BY E. FLETCHER INGALS, M.D.,

CHICAGO.

IN the *Journal of the A. M. A.*, February 21, 1914, I published a short article on this subject, referring to three cases on which I had operated and including also a case report by Dr. Stanton A. Friedberg. I think both of us now realize that the article was liable to misinterpretation by the general practitioner who might conclude that with the aid of the fluoroscope the operation might be safely attempted by almost anyone. Such an impression would be a misfortune, for it would undoubtedly lead to disastrous results in many cases; but to the well-qualified bronchoscopist the method will prove a valuable aid in certain difficult cases where the usual procedure has failed.

In inexperienced hands bronchoscopy for the removal of foreign bodies has been attended by a very high mortality, similar to that from splenectomy or deep gall duct operations, and I have no doubt that under similar conditions it will be equally serious in the future; but as individual operators grow more and more skillful, the mortality should steadily decrease until it should be no greater than from laparotomies with operations upon the pelvic organs. Nevertheless, even the most skilful must necessarily fail in some instances and fatal results will occasionally follow. I am satisfied that fluoroscopic bronchoscopy will lessen the danger and decrease the number of failures in the conditions where it is indicated.

I think this operation is indicated in all cases in which the foreign body casts a shadow with the *x*-ray where the ordinary method has failed; but more especially, in the following classes:

1. Those in which there is so much mucus, pus, or blood that it is very difficult or impossible to see the foreign body.
2. Those where granulation tissue covers the foreign body.
3. Those in which the body is hidden, in an abscess cavity.
4. Those in which a stricture has formed proximally to the foreign body.
5. Difficult cases in which the body is lodged in a bronchus going to the upper lobe of the lung, or in any bronchus where it cannot be exposed by ordinary methods.

In this procedure one should have a good *x*-ray apparatus and the assistance of an experienced radiographer. Usually no anesthetic is required and it is much better to get along without it if practicable. It is specially important to have a narrow strong forceps with which one is not likely to do damage and one that will not slip when the object has been grasped.

The patient is placed on a special table with the *x*-ray tube beneath it; and it may be necessary to have a board on which the patient may lie raised four inches above the table, in order that his head may hang over the end. This is desirable because the position of the tube beneath the table makes it difficult to bring the patient's body near enough to the end of the table so that his head may hang over it.

With the fluoroscope ready the bronchoscope is introduced into the trachea and carried down as nearly as practicable to the foreign body. The *x*-ray is then turned on. The surgeon, standing at the left side of the patient's head and holding the bronchoscope with his left hand, directs it by the shadow toward the foreign body. The forceps, held by his right hand, is passed through the bronchoscope , and by its shadow guided down to the foreign body. It should then be moved back and forth laterally to ascertain whether it is in the same bronchus or cavity with the foreign body—if not, or if it is in front or back of the latter, its shadow will pass beyond the shadow of the foreign body with these movements. If this occurs, by gentle manipulation the forceps must be repeatedly passed in somewhat different directions until a position is attained where the shadow of the foreign body moves laterally with that of the end of the forceps. The blades are then opened and the forceps passed down a little farther so as to grasp the foreign body. Several attempts may be necessary to accomplish this, especially if the foreign body is in an irregular abscess cavity; but when it is in a bronchus there should be but little difficulty. When the foreign body has been seized and is shown to be coming with the forceps, the surgeon should not let go until it is brought out, even though considerable traction may be necessary to draw it through a stricture. The operator may grasp the pulmonary tissue instead of the foreign body but by care and gentleness this can be discovered so that injury may be avoided. One should make very little traction until certain that he has only the foreign body,

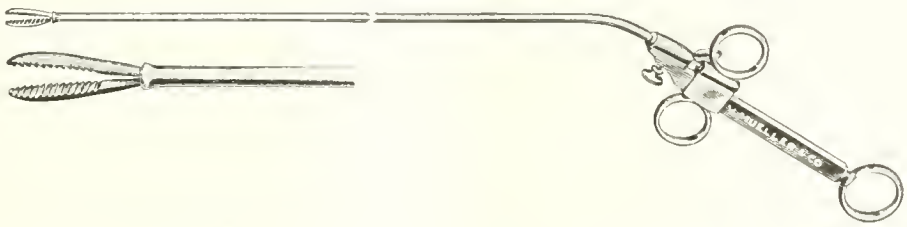
*Presented at a meeting of the American Laryngological Association, Niagara Falls, Canada, June, 1915.

but when assured of this I think that from 5 pounds to even 10 pounds might sometimes be justifiable, according to the condition of the lung. This, however, must be left to the judgment of the operator.

The forceps I recommend for this operation is a simple narrow, very strong tube forceps to which is attached a Krause handle.

The face of the blades is cut like a file with the sharp edges toward the handle. The tube, and the blades when closed, are only 4 mm. in diameter. This is an excellent forceps for nearly all work within the bronchi or trachea excepting when the foreign body is of such a nature that it is liable to be crushed.

The cases recorded in my former paper each possessed some special interest and the two cases now reported further illustrate the utility of this method.



Strong tube forceps with file-like surface to blades; 4 mm. in diameter. Krause handle.

Case I.—The first of these was sent to me by Dr. Bullock of Silver City, N. M. The patient, S. W. P., had aspirated a nail two years previously but no one believed that it had passed into his air passages. After the accident he was thought to be suffering from stomach trouble, and he had a good deal of cough with expectoration of some pus and blood and pain in the right chest which finally led to the belief that it was tuberculosis; for which he went to Dr. Bullock's Sanatorium. On making an *x*-ray examination, Dr. B. found the nail. I saw the patient first April 16, 1914, immediately after my return from California, and attempted a bronchoscopy in my office under cocaine, but the patient's throat was very irritable and he jerked the tube out of the trachea before I could see anything.

The *x*-ray showed the nail at the lower part of the right lung below the fifth rib in front, and between the ninth and eleventh ribs behind. Laterally the shadow was shown about 2½ inches in front of the spinal column. Because of the irritability of the throat, I decided on lower bronchoscopy and because of the depth of the nail, the time it had been in the lung, the probability of an abscess cavity, and the amount of purulent secretion, I prepared for fluoroscopic bronchoscopy. Assisted by Dr. Stanton A. Friedberg and some of the house staff, I did tracheotomy under local anesthesia, then took the patient to the dark room and introduced the bronchoscope. I found the bronchus so filled with granulation tissue that it was impossible to see anything below it. I then used the fluoroscope and with the forceps already referred to quickly removed the nail without pain or discomfort to the patient. The patient did well afterward and was discharged from the hospital as soon as the tracheotomy wound had healed. I heard from him recently and he appears to have made a perfect recovery.

Case II.—I recently saw a little patient for Dr. M. L. Goodkind at the Michael Reese Hospital, Chicago, in whom the history and the fluoroscope had shown a metallic foreign body in the right lung. The patient M. H., aged 5 years, last October told the parents he had swallowed a rivet. The subsequent symptoms had been attributed to the stomach. Following the accident, the boy had been very ill for about three weeks, and he was subsequently under medical care off and on, until about three weeks before he was sent to Chicago; at that time he was said to have developed a pleurisy and had since been coughing and running a temperature of from 102° to 104° F. every afternoon, but there was no expectoration.

The fluoroscope anteroposteriorly and laterally showed the position of the foreign body distinctly and from the negative it was located in the second interspace 2 cm. to the right of the middle of the sternum. We wrapped the child securely in a blanket and without any anesthetic, excepting a little cocaine to reduce coughing later on, I did bronchoscopy, assisted by Dr. Stanton A. Friedberg and Dr. Ralph B. Bettman and other hospital physicians; but we were unable to discover the foreign body even after a careful search for nearly an hour. Although 1/250 of a grain of atropine had been given hypodermically half an hour before the operation, the mucus and mucopurulent secretion was so abundant that more than 9/10 of the time was occupied in swabbing it out. We carefully explored the whole length of the right trunk bronchus which was free far below the foreign body; but we could not see into any lateral branch. The secretion appeared to come from a narrow opening at or near the site of the first division of the right main bronchus; but on account of the difficulty caused by the secretions even this could not be definitely located.

Finally, feeling that the child should not be subjected to a longer examination, I desisted. The patient had coughed a good deal during the operation, but he admitted that it had not pained him. I directed that the child be kept in a croup tent for 48 hours and given 2 drs. of liq. amm. acetatis four times a day. Following the operation the patient did very well indeed and I found him feeling comfortable next morning. The temperature 101.5°, pulse 125. The following day the temperature went up to 102°.

Three days later the pulse varied from 92 to 120 and the temperature from normal up to 100° F. With the same assistants and Dr. Frances Turley, the radiophagist, I did a fluroscopic bronchoscopy. When everything was ready, Dr. Friedberg introduced the bronchoscope for me and assisted me in holding it with my left hand while I managed the forceps with my right. I missed the track to the foreign body a couple of times and grasped soft tissue three or four times before I felt sure that I had seized the iron. I drew it out carefully, with 2 or 3 pound resistance, as it came through the stricture with a snap, and then brought it out at the end of the bronchoscope. It proved to be a smooth iron cylinder, part of a rivet, 6 mm. in diameter and 8 mm. long. It was a body difficult to hold but the forceps did not slip at all after really grasping it. The patient was put in a croup tent again for 24 hours. The morning following the operation he was in fine condition, respiration 22, pulse 88, temperature normal. The same day exploratory aspiration demonstrated a serofibrinous fluid in the pleural cavity. The following day the conditions were the same, the cough and fever had disappeared, and the patient was allowed to go home.

On May 11 I assisted Dr. Stanton A. Friedberg with this operation on a child who had an upholsterer's tack in a lung cavity with a proximal stricture which had rendered ordinary bronchoscopy futile, the history of which is herewith appended by Dr. Friedberg.

On March 17, the patient a girl, 12 years of age, had aspirated a brass-headed upholsterer's tack. The accident was followed by an attack that was called septic pneumonia. Previous to my seeing her, tracheotomy had been done and two attempts at removal had been made. I saw the patient first May 8 and did a bronchoscopy through the existing tracheotomy wound. Over an hour's time was spent mostly in removing pus and secretions. A stricture was found in a secondary bronchus of the right side through which I was unable to pass the smallest tube. A forceps passed through the stricture gave evidence of a considerable cavity. Further effort was postponed until the patient could be brought to Chicago. On May 11 the second attempt was made; with the assistance of Dr. Ingals, the bronchoscope was passed to the site of the stricture through which the forceps was introduced. Through the screen the move-

ments of the tack and forceps could be plainly followed. When the tack was secured the jaws of the forceps could be seen to be partly opened. Removal was accomplished without difficulty by pushing the end of the tube down while the forceps and tack were brought upward. When the tube met with the head of the tack they were both withdrawn. No ill effects were experienced from the operation, which was done without anesthesia.

104 South Michigan Avenue.

CARCINOMA OF THE CECUM WITH EXTREME PTOSIS OF THE ABDOMINAL VISCERA.

By M. R. SMIRNOW, M.D.,

New Haven, Conn.

Cases, both of carcinoma of the cecum and of ptotic viscera are so common and the literature is so full of them that it is with the greatest amount of hesitation that the writer desires to record this one. The fact of the rather peculiar and extreme condition found, he hopes, will make it pardonable.

The case is that of an American woman aged 74, white, single, who entered the New Haven Hospital, Nov. 21, complaining of swelling and pain in the lower right abdomen. She had noticed a "swelling" in this location for four months previous and first felt "soreness" several weeks before her entrance to the hospital. On account of extreme deafness, no further history was obtained.

Physical Examination. (Dr. Comfort, resident physician, surgical staff.) "Patient much emaciated and poorly nourished. Skin has a yellowish tint, markedly pale, dry and loose from emaciation. Pupils small, react slowly to light and accommodation; slight arcus senilis, sclera clear. No paralysis of facial or ocular muscles, eyesight poor. Patient is very deaf. Her mucous membranes are pale. The tongue is moist and fairly clean. Pharynx is negative. Few small palpable cervical glands are present. Epitrochlears are not enlarged. Slight edema present over tibia. Reflexes are normal.

"*Chest.* Small; prominent supra and infraclavicular spaces; intercostal spaces also prominent; marked scoliosis to the right. Breasts atrophic. Lungs—expansion poor (palpation and percussion of lungs not recorded, presumably on account of weakness of patient). Roughened breath sounds at both upper lobes. Few moist râles at the end of inspiration posteriorly on the left just above scapular spine. Heart—left boarder 10 cm. from midsternal line; apex in the fifth interspace in the nipple line; right boarder at right sternal margin. A systolic murmur, soft and blowing, heard at apex and transmitted toward the axilla. The second aortic is louder than the second pulmonic, both sounds being accentuated.

"*Abdomen.* Somewhat distended. There is a prominence in the right lower quadrant. This mass is very evident, occupies the position of the cecum, is very tender, irregular in outline and more or less nodular in character. A little tympany is made out above the mass. Liver dullness extends from the third interspace to the level of the umbilicus, the surface of the liver is smooth and rather tender. The remainder of the abdomen is dull; considerable fecal matter in the bowel. No fluid made out. Left side not tender and negative to palpation. Vaginal examination not made."

The above physical examination was verified by Dr. Hawkes, of the visiting surgical staff.

Diagnosis.—Inoperable carcinoma of the cecum.

During the patient's stay in the hospital, her condition remained the same. She had no increase in temperature, her pulse rate varied from 80 to 100 and her respirations were about 20. Her urine showed a slight amount of albumin, an occasional granular cast and few leucocytes. The blood examination showed 4,350,000 reds, and 11,000 whites with 66 per cent. polymorphonuclear and 25 per cent. small non-nuclear leucocytes.

On Jan. 6, her temperature suddenly went up to 102.5° F. (axillary) from a subnormal (96.8°) on the day before. It fell just as suddenly as it rose, in about fifteen hours, and remained at 97° F. until death. Her heart rate increased to 120 beats per minute, and stayed there until death, accompanied by an increase of respirations, varying from 50 to 60. She died at 9 A.M. of Jan. 7.

Autopsy, Jan. 7, 3 P.M.,—6 hours post mortem. *External Examination.*—Body that of a woman 153 cm. in length, approximate weight 90 lbs. or less, of slight build,—and poorly developed. Color is pale with slight yellowish tinge to body, most pronounced in the face. Emaciation extreme and general, breast tissue practically disappeared; supra and infraclavicular spaces, likewise the intercostal spaces very pronounced. Sclera pale, somewhat yellowish, pupils small, mucous membrane of mouth and lips pale. Rigor mortis marked and general; lividity slight in dependant portions of body. Slight amount of edema over ankles. A large tumor mass is seen in the right iliac region. This mass is about the size of a large orange, irregular in outline and nodular. Another mass, elongated and more regular in outline, is felt to the left of the median line in the umbilical region. Axillary and inguinal glands not enlarged. A marked scoliosis to the right and a marked lordosis are present. Several incipient bed-sores are seen over the sacrum.

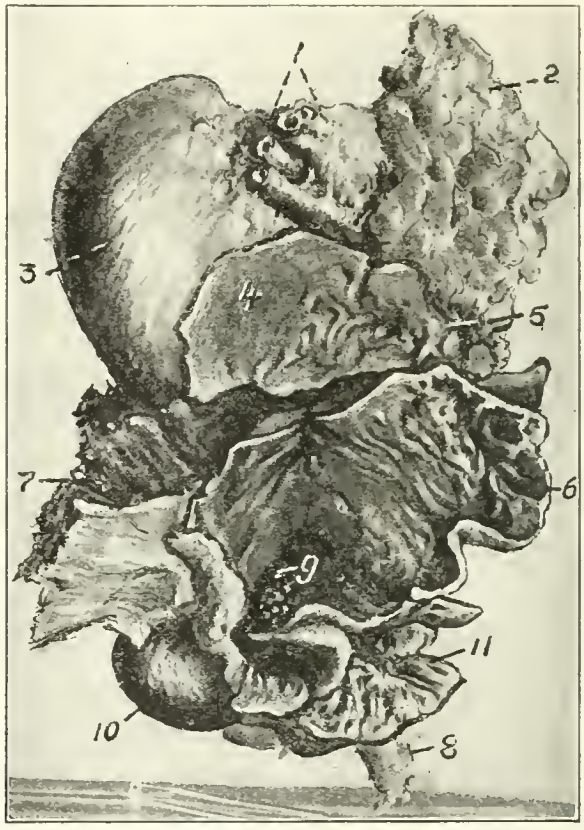


Fig. 1.—1. Common bile duct and hepatic artery, portal vein. 2. Pancreas. 3. Right kidney. 4. Stomach. 5. Duodenum. 6. Ascending colon. 7. Psoas muscle and part of pelvic wall. 8. Mesentery. 9. Tumor. 10. Cecum. 11. Small intestine.

Abdominal Cavity.—The abdominal walls very thin, fat practically gone. The abdominal cavity contained no fluid. The tumor mass mentioned under external examination, was found low down in the right iliac region and extended below the ileopectoneal line into the true pelvis. The omentum was adherent both to the upper surface of this mass and also to the anterior abdominal wall. The stomach was markedly elongated, tubular in shape and extended diagonally from the left hypochondriac to right iliac regions, its pyloric end being adherent to the tumor mass. Ptosis of all the abdominal organs is marked. The pancreas accompanied the stomach and was seen to lie partly parallel and partly posterior to the stomach. It was much elongated and flattened and was covered only by a layer of peritoneum (gastrohepatic omentum) which separated it from the anterior abdominal wall. The head of the pancreas also helped to form part of the mass. The liver extended from 8 to 10 cm. below the free margin of the ribs. The gallbladder was quite elongated. The right kidney was somewhat larger than normal and its pelvis was enlarged and markedly distended with fluid. It was found to lie immediately above the iliopectoneal line and helped

to form the mass described. The cecum was somewhat distended but felt firm. One or two loops of intestine was adherent to the mass. The position of the duodenum was remarkable. This portion of the gut was also displaced downward; it lay above and to the inner side of the mass described, running from the pyloric end of the stomach and tumor mass, downward into the true pelvis then curving upward over the promontory of the sacrum. The spleen was small, ptosed, but not adherent. The left kidney was somewhat ptosed. The dome of the diaphragm extended to the fifth rib on the right and the fourth rib on the left. The uterus was small, the left ovary and tube were free, the right was adherent to the tumor mass.

Chest Cavity.—There was no fluid in either chest cavities. The lungs were free except for a few fibrous adhesions between their bases and the diaphragm. The pericardium contained the normal amount of fluid and was normal in all other respects.

Heart.—Weight, 255 gm., was smaller than normal, contracted but not firmly so. The pericardium showed large white milk patches over the greater part of its

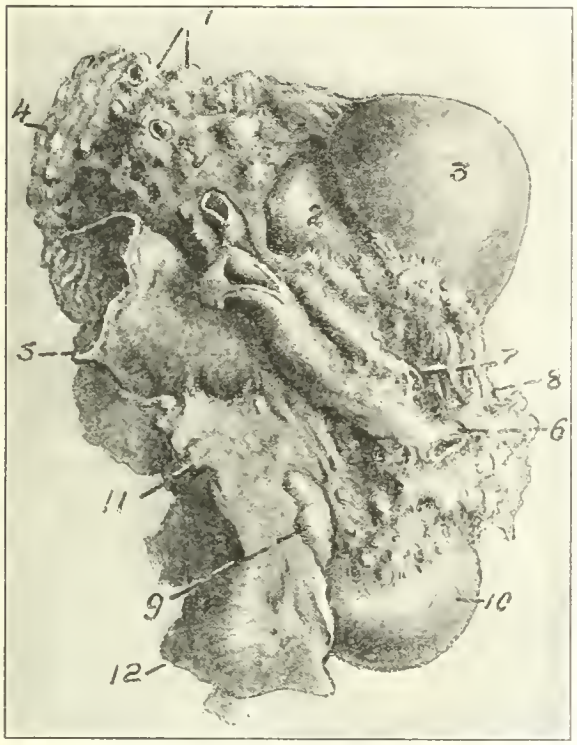

Fig. 2.—1. Common bile duct and hepatic artery, portal vein. 2. Pelvis of right kidney, showing hydronephrosis. 3. Right kidney. 4. Pancreas; superior mesenteric artery crossing it. 5. Duodenum. 6. Common iliac vein and vena cava above. 7. Internal iliac artery, common iliac above. 8. Psoas muscle. 9. Appendix. 10. Cecum. 11. Mesentery. 12. Ileum.

surface. Fat was rather abundant but had undergone serous degeneration. The vessels were rather tortuous. The mitral orifice measured 9 cm., free margins normal in thickness. Chordæ tendinæ much shorter and thicker than normal. Aortic valve was 7 cm., its cusps were moderately thickened and slightly bound together, but competent. Tricuspid valve measured 10.5 cm. normal; the pulmonic, 6.5 cm., also normal. The myocardium was reddish-brown in color, of good consistency, and measured 1.5 cm. on the left and 4 mm. in thickness on the right.

Lungs.—Right apex was somewhat retracted, surface smooth, presented one or two old adhesions at apex and at base. Upper lobe crepitated but slightly and had several larger and smaller modules of very firm consistency. The middle and lower lobes crepitated throughout. The anterior boarders were pale and emphysematous. Cut surface of the lungs, showed in the upper lobe several masses of gray, firm fibrous tissue, in places containing calcareous deposits and black pigment. Bronchi showed small quantities of frothy mucus. The lower lobes showed a large amount of frothy reddish fluid on squeezing. No pneumonic areas were present in gross but were found later under the microscope.

Liver.—Weight 870 gm., very small, surface smooth, capsule markedly thickened over upper surface of left lobe, margins much thinned out, the anterior border of the left lobe being almost transparent. Cut surface showed the tissue to be pale, yellowish gray in color and somewhat bile stained, the lobules were much smaller and their boundaries indistinct. Its consistency was much less than normal.

Spleen.—Weight, 85 gm., was much smaller than normal, capsule smooth; cut surface, normal color and consistency; on account of the atrophy the trabeculæ appeared more pronounced. The Malphigian bodies were distinct.

Right kidney removed with tumor mass, was already described. Left kidney: weight, 140 gm., capsule stripped easily leaving a slightly roughened surface; consistency about normal. The stellate veins were somewhat more distinct than normal. Cortex was of normal thickness, markings were quite distinct. The pyramids and their markings were normal. Few of the arteries stood open. Microscopically some of the glomeruli were replaced by fibrous tissue, the interstitial tissue was but slightly increased. The parenchyma was in general good condition, some of the arteries showed arteriosclerotic change.

The stomach was markedly elongated and contracted, otherwise normal, pyloric end adherent to tumor mass.

The pancreas was elongated and flattened, the head of the pancreas being included in the tumor mass.

The adrenals were normal.

The intestine with the exception of its malposition, and the lesion of the cecum which will be described below, was normal.

The bladder was normal.

The uterus was atrophied very firm and hard to cut, otherwise normal.

The ovaries were atrophied and sclerotic. The right ovary was adherent to the tumor mass.

The aorta showed numerous arteriosclerotic placques, some of which were calcified.

The Tumor Mass.—What is here spoken of as the tumor mass indicates not the tumor *per se* but also the cecum and the parts of the various organs adherent to it as removed at autopsy and shown in the illustrations. The general description and location of this mass has already been given, and will not be repeated, except to call attention again to the fact that the greater part of it and parts of the various organs attached to it were found below the iliopectoneal line and in the true pelvis. Anteriorly the mass of tissue was covered by the omentum and a few loops of small intestines held in place by a few light adhesions. Posteriorly it lay upon the psoas and obturator internus, pyriformis, and coccygeal muscles, and covered the common, external, and internal iliac arteries and their veins.

The tumor itself was in the posterior wall of the cecum and beginning of the ascending colon. It presented a very roughened papilliform surface and was black in color. The walls of the cecum were infiltrated by the tumor and also markedly thickened by chronic inflammatory changes. Microscopically the tumor proved to be an adenocarcinoma. It is noteworthy that there were no metastases.

Mention has been made of another tumor-like mass found on external palpation of the abdomen. This proved to be the anterior surface of the spinal column brought forward by the extreme lordosis and made more evident on account of the emaciation of the body.

Anatomical Diagnosis.—(1) Adenocarcinoma of the cecum. (2) Extreme cachexia and emaciation. (3) Marked distortion and ptosis of all abdominal organs. (4) Senile atrophy of the heart, liver, spleen, uterus, ovaries. (5) Chronic endocarditis with mitral insufficiency, chronic pericarditis, and serous degeneration of pericardial fat. (6) Healed tuberculosis of lungs, emphysema, chronic pleurisy, and terminal bronchopneumonia. (7) Chronic interstitial nephritis, hydronephrosis of right kidney. (8) Scoliosis and lordosis. (9) Chronic localized peritonitis. (10) Arteriosclerosis. (11) Jaundice.

Hereditary Familial Osteopsathyrosis. — Tillaye reports the history of a family of six children every one of whom, together with their father, sustained one or more fractures in the course of their life. In every instance the trauma was insignificant and the femur was the bone most frequently fractured.—*Revue d'Orthopédie.*

SYPHILITIC REINFECTION WITH NOTES ON IMMUNITY AND TREATMENT.*

By FREDERICK W. SMITH, M.D.,

NEW YORK.

INSTRUCTOR IN GENITOURINARY AND VENEREAL DISEASES AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

My patient is a man now fifty-two years of age. From all the history obtained I gathered no facts of previous illness or inherited taint relevant to the conditions I am reporting. He is a man of considerable education and refinement.

Upon the latter qualifications I have to depend somewhat for the intelligence and truthfulness of the history of his previous syphilitic infection, which occurred in 1886. He recalls an indurated persistent genital lesion, followed several weeks later by skin manifestation which were sufficient to convince the late Dr. Charles K. Briddon, then Attending Surgeon at the Presbyterian Hospital, New York City, a man of unquestionable skill, that the patient was infected with syphilis. He was given the usual sugar-coated granules containing 1-5 grain of protiodide, so popular at that time, and instructed to increase the dosage until free catharsis and salivation ensued, then to decrease the dose gradually and again repeat the course. This treatment was continued for two years. Four years later, namely, in 1900, he developed disease of the middle turbinated bones with caries and necrosis, involving, and causing perforation of, the hard palate, for which he now wears a plate and obturator. The condition was diagnosticated uncured syphilis and treatment was resumed, this time by deep intramuscular injections of mercury, and was continued for some time. From then until the onset of the second infection, he enjoyed good health. On October 29, 1912, he reported to me with a genital lesion on the left side of the penis, above the corona glandis, which he said appeared ten days before, and, as we learned later, two weeks after an exposure. It was not an ulcer, but an erosion on the same level as the adjacent tissues, and was hard and indurated. The inguinal glands on both sides were palpable, each gland separate and distinct, insensitive, hard and indolent. The picture was not one of persisting virus activity, but of a new infection. However, the patient was not so easily convinced. Smears were then made from serum obtained by curetting the untreated lesion, and the *Treponema pallidum* was demonstrated. A Wassermann test was made, and found negative, which further convinced me that the patient had recovered from the former infection. As the lesion was of only ten days' duration and the time required is usually over two weeks after the first appearance of the chancre, I concluded that sufficient time had not elapsed to produce a positive test from the latter infection, as it is necessary for the disease to have been in existence for a certain time to allow antibodies to develop.

Treatment was immediately begun with an intravenous injection of neosalvarsan, dosage No. 111, with the first intention of relieving the patient quickly of his symptoms, and the second of testing the effect on his former infection of this provocative measure. Five days later the Wassermann test was still negative. Ten days later, or twenty-seven days after the first appearance of the initial lesion, a positive test was obtained, thus proving to a high degree of certainty that the former infection had been cured. The evidence of a previous attack seemed quite positive, and I had convincing evidence of a second infection.

That reinfection with syphilis is possible, is acknowledged by a great majority of the older syphilographers, but that the occurrence is rare is manifest by the few cases reported in the centuries through which the disease has been recognized and treated. Some writers of repute believe that it never occurs. Sir Jonathan Hutchison relates at some length the case of a young surgeon who contracted syphilis in 1860, and again in 1865. Rodet mentions two cases. Diday has reported twenty cases, but many of them are open to question, for according to him, the usual secondary symptoms do not appear after the second infection, but after the so-called initial lesion of the reinfection, tertiary manifestations classed as gummata, nodes and deep serpiginous ulcerations follow within a short time. These may have been simply the manifestations of the primary infection. Probably the described initial lesion was a common tertiary manifestation, the so-called "chancre redux" which mimics in every detail the original chancre, for any part of the integument or mucous membrane upon which an initial lesion has existed may, at any time in the course of syphilis, be the seat of recurring nodules, which are liable to be mistaken for primary lesions.

Some of our well-known American syphilographers, concurring with Diday, seem in the light of our present knowledge to be also in error. From a monograph by a recognized authority, the late Dr. Prince A. Morrow,[1] we read about "the very rare but nevertheless well-authenticated cases of syphilitic manifestation in which the patient may exhibit the characteristic lesion of a second attack, while he bears upon his person the stigmata, or it may be the active manifestation, of a former attack. . . ." And Lydston,[2] commenting on cases of reinfection during the tertiary stages, writes that "a few of Diday's cases were contracted during the existence of tertiary manifestations of the previous attack, and this, too, he states, is an important fact as tending to show that typic tertiary lesions are not syphilitic at all, but simply non-transmissible sequels."

In Professor Fournier's excellent writings on syphillis, we find that he is not convinced that reinfections occur.

I also quote a paragraph from the American textbook edited by Bangs & Hardaway,[3] which expresses an opinion coinciding with Fournier. It states that "an individual who has once had syphilis is rarely thus infected a second time, and a large majority of the cases reported as acquiring the disease after a previous attack are open to much doubt."

From Dr. Keyes's[4] recent monograph, I conclude that he believed reinfection to seldom, if ever, occur, for he states: "All that one can safely allege is that there is only an infinitesimal danger of error in assuring one's patients that syphilis boasts a solitary virtue, viz., having acquired it once, they will never acquire it again."

Clinical manifestations alone cannot *now* be relied upon to determine the question, and I dare say that in the past the results were often unsatisfactory and sometimes even disastrous. The parasitologic, and usually the serologic, findings are absolute. They, as a rule, act as a forerunner to the developing clinical picture, and give the necessary information in time to institute treatment in anticipation of the awakening disease. Thus we avoid delay, the physical and social annoyance of secondary symptoms, and some at least of the unfortunate after results, for if secondary symptoms have once appeared, the course of treatment must be longer, and the prognosis, though good, is less favorable. In the tertiary period a serologic cure, or negative Wassermann test, is sometimes difficult to obtain, and even this is not a guarantee that the disease is eradicated as encapsulated spirochete may still remain. The biological reason for this may be physical as well as chemical.

When we consider the histological structure of a gumma, with its whitish-yellow central slough, devoid of blood vessels, surrounded by a zone of loose

*Read before the Section of Genitourinary Surgery at the New York Academy of Medicine, April 21, 1915.

connective tissue, while the periphery of the tumor is constituted by a round-celled hyperemic infiltration of the normal tissue of the part involved and an endarteritis with obliteration of the lumen of the smaller vessels has occurred, it seems probable that the spirochetecide remedies may not reach these circumscribed areas, either through the blood or lymph, but toxins may be generated within them and eliminated, causing the Wassermann test to remain positive. Then again the virus may become locked up in the inaccessible subarachnoid lymph space, or in the nerve cell layers of the cortex and not in the vicinity of the larger blood vessels.

According to Mott[5] "the spinal fluid is not lymph, but a secretion of the cells lining the choroid plexus and the arachnoid." Drugs introduced into the blood stream, or absorbed into the blood, finally pass into the lymph spaces, where also the antibodies are formed, but as the cerebrospinal fluid is not lymph, these antiluetic principles cannot destroy the inaccessible spirocheta. Flexner[6] states that "we are just learning that in tabes, and shall probably learn that in paresis also, it is the special localization of *Spirochæta pallida* in the central nervous system tissues, in situations accessible to the craniospinal fluid rather than to the blood, that has so largely determined the failure of almost every effort to combat these now established syphilitic affections by the usual antisyphilitic remedies." Again, possibly as a result of treatment with specific drugs or in the developing processes of immunity, the treponema may acquire a state of resistance to the accustomed curative agents, and become no longer subject to their influence, inducing a condition of "fastness" which would result in troublesome and serious relapses within the host, and probably a continued positive Wassermann test.

Certain it is that after the development of the tertiary symptoms, the disease enters into a stage in which the complete destruction of every treponema is increasingly difficult. Clinically the virus may remain quiescent for many years, the Wassermann test may be negative, yet when all too late parasyphilis ensues. Probably the only absolute proof of cure is the possibility of reinfection, as apparently occurred with the patient I am reporting. This shows that his tissues had returned to their normal degree of vulnerability, which could not happen if spirocheta were still present in his body. Real immunity to protozoal disease is short lived. As yet but one variety of the *Treponema pallidum* has been demonstrated. In consequence, we have to consider that my patient was no longer immune to this organism. However, in this connection it is well to bear in mind that according to Pasteur there is no such thing as absolute immunity, because if the infection is large enough and virulent enough even an immune individual will again contract the disease.

In the past we had no absolute knowledge as to cure, except our own judgment that the proper amount of mercury had been consumed during three or four years, and the fact that the patient had remained free from symptoms for a comparatively long time. That we were in error and that most of the patients, however well treated, still harbored latent syphilis, is proved by the fact that reinfection with syphilis was so very rare. Since the advent of salvarsan into the treatment, cases of reinfection have occurred frequently and usually within a short time, showing that recovery is positively and quickly accomplished.

A few years ago errors in diagnosis and treatment were due to pardonable ignorance, but today, with modern serological tests and laboratory methods for determining the presence of the pathogenic organism—a parasite which has fulfilled the three requirements of Koch's postulates — diagnosis should be made promptly, treatment instituted early, and, if managed properly, so-called parasyphilis which is really a late stage of actual syphilis should be avoided. A properly performed Wassermann test not only tells us that the patient has syphilis, but the degree of constitutional infection, or amount of natural resistance. For this reason a uniformity in technique and a standardization of reagents should be adopted by serologists. A standard method for reporting the degree of infection or resistance should be adopted, allowing for comparison with previous examinations, as an index of the result and as a guide to us in our treatments.

The dictum of a few years ago, "Wait for the appearance of secondaries, then treat the patient for two or three years with mercury and then potassium iodide; hope for a cure of most cases, but expect parasyphilis in a few and relapses in some" should be revised, as should many chapters in the older text books. However, it is pleasing to note that such a keen observer and eminent authority as the late Dr. Robert W. Taylor, from his study of a vast number of cases, concludes in his excellent monograph on syphilis[7] that "there is no doubt whatever in my mind that a mercurial treatment covering the first six months of the disease is more salutary and effective than a course extending over a year or more instituted later on. It is important, therefore, that the initial course should be active and prolonged."

And even so today, as soon as the diagnosis is established, intensive treatment should be instituted. When the infection is regional and not markedly systemic, or when the parasites are widely disseminated throughout the body, but accessible, the curative drugs assert their curative power with far less difficulty and far more certainty than when the germs are hidden away within an organ, or when encapsulated, or in the interior of a cavity. Salvarsan, or neosalvarsan, should be given intravenously every week or ten days for at least six injections, and between the treatments mercury in some form should be given, preferably by deep intramuscular injection. Inunctions cannot well be employed outside of a suitable institution, and I have seen patients who have been treated with mercury pills for as long as six years show positive Wassermann tests, and even active lesions of the skin and mucous membrane. Salvarsan and mercury are synergistic drugs, and together are most effective in treating syphilis. If the disease is malignant in form and particularly virulent, or if the patient is unusually asthenic, it is sometimes well to administer a few injections of mercury before beginning a course of salvarsan, and by so doing prevent a cerebrospinal toxemia due to lysis of the many protozoa destroyed by the assault of the more powerful drug, salvarsan.

After this course of medication in the case reported, I suspended treatment for a month, and then found the Wassermann test negative. However, desiring to give the patient the benefit of any doubt, I repeated the entire course of treatment, and since then, with treatment suspended, I have found with him, as with a series of similar cases where treatment had covered a period of less than six months

duration, that the Wassermann tests have remained negative until the present, or from one and a half to two years, and I find no clinical manifestations of the disease.

It would be quite useless to draw any inference from a negative Wassermann test had it not previously been positive, as it sometimes spontaneously becomes negative in the tertiary stages.

At the end of a year, having had several negative tests during this time, I gave a provocative injection of dosage 111 neosalvarsan, and ten days later the blood was again tested and the Wassermann reaction found negative, as have several tests since. In the light of our present knowledge, I must conclude that he is cured; but time alone will determine the permanency of the cure.

THE WASSERMANN REACTION ACCORDING TO WASSERMANN HIMSELF.

By E. PALIER, M.D.,

NEW YORK.

The purpose of this paper is not to reveal anything new but to clarify and establish something that is comparatively old, which unfortunately has been distorted by those who cannot grasp the data as laid down by a master mind.

If one should look for an easy, comprehensible, detailed description of the Wassermann reaction, one will have a hard task to find it. Most of the articles I have seen on the subject were limited to generalities, while many of those who go into some details are wrong.

Some two years ago I had the good fortune to attend the lectures and demonstrations on this subject by Wassermann himself. The following little story told by him is instructive: Once in passing a street he noticed a sign stating that the Wassermann reaction was done inside. He was curious to know how it was done. He went inside, introduced himself and said he wished to know what was being done with his name. The man explained how he did it.

"The man did not know anything about it," said Wassermann.

Some five years ago the writer of this spoke on this subject with a recent graduate who served as an interne in some home for invalids, in New York City, and who for some reason unknown to the writer had gotten a reputation as an authority on the Wassermann reaction, so that his articles on the subject were solicited and published by the medical press, the articles in fact limiting themselves to generalities. He told me that the red corpuscles of a goat were used in this reaction! As the reagents were not yet then on the market, one can imagine how he did this reaction. I make this rather lengthy introduction to show how little this reaction is generally understood even in Germany. I will not deal separately with the preparation of the several reagents entering into this reaction, as I have mainly the clinical side in view, but will describe them briefly as we proceed.

Now, whereas the clinical part of this reaction is, according to my view, not more difficult than ordinary uranalysis, provided one grasps the idea of it and is somewhat used to laboratory manipulations, the preparation of the reagents entering into this reaction requires a laboratory expert. I will say here that these reagents are put up under the direction of Wassermann himself by the Pharmaceutic Institute of Ludwig Miller of Oberusel, a. F., Germany.

In order to perform the reaction in question it is necessary first to obtain the blood of the patient to be tested, and the several ingredients which will be described immediately. In order not to perplex the mind of the reader who may not be initiated into Ehrlich's lateral chain theory and the deviation of the complement, I shall better briefly mention the principles underlying this reaction at the end, after describing the purely technical part. The patient's blood is best obtained aseptically from the median vein of the arm. In Paris they conveniently use a simple rubber tube, like a stomach tube, which is placed around the arm, under the axilla, both ends of the tube being grasped by an artery forceps. By making the patient close and open his hand the vein stands out prominently. A long needle of medium size is then introduced, and as soon as there is a flow of blood the bandage is removed from the arm and the blood is received in a sterilized test tube. A few cubic centimeter suffice. The test tube is then allowed to stand till the blood clot separates, when the clear serum is poured off into another sterilized test tube. Then it, the serum, is placed in the incubator for *half an hour* at a temperature of 56° C. When there is no incubator, a water bath with a good theremometer will do. The serum must be kept in a cool place if it is not to be tested immediately. Next we need the several reagents which we shall briefly describe:

1. Serum from a positively syphilitic patient.
2. Serum from a positively non-syphilitic patient.
3. Antigen. We shall say below a few words concerning antigen in general. The antigen for the reaction in question is the substance which forms a combination through the medium of the complement, to be described soon, with the serum of a syphilitic patient. It is prepared according to Wassermann from an alcoholic extract of a syphilitic liver from a dead congenitally-syphilitic child—I gram of finely divided syphilitic liver is macerated by frequent shaking in 50 grams of 96 per cent. alcohol. After a few hours it is centrifuged, decanted and the liquid part used. Watery extracts, also non-syphilitic liver and other substances are used by many. But this is not in accord with the Wassermann teaching.
4. The red blood corpuscles of a sheep. It is the red blood corpuscles that are used, not the whole blood, as I saw stated in a German booklet on the subject. Fresh sheep's blood is centrifuged, the serum is poured off, then physiological salt solution, *i.e.* 0.85 per cent. salt solution, is added, so as to make up the same volume as before, and centrifuged. This washing of the corpuscles, as it is called, is repeated several times with the salt solution, always

adding it up to the same mark. Five parts of these washed corpuscles are added to 95 parts of physiological salt solution for use.

5. The amboceptor. We shall say a few words about it soon. In this case it is prepared by injecting red blood corpuscles treated in the way stated above into a rabbit intraperitoneally; 20 c.c. of the above 5 per cent. suspension, which will amount to 1 c.c. of a concentrated suspension of blood corpuscles, are injected into a rabbit a few times at intervals of about 7 days. Then the blood from the rabbit is obtained and the serum prepared and kept the same as was described for preparing the patient's serum.

6. Complement. Whereas the above named reagents do not quickly deteriorate on keeping, the complement must not be older than 24 hours. In a frozen state it can be kept a little longer. When one does not live within easy reach of a reliable laboratory, he himself will have to prepare the complement, while he can get the other reagents from any distant place. The complement is obtained from the blood of a guinea pig. When only a small quantity is necessary, blood can be obtained from the heart by inserting a needle, or from an ear vein. The latter method is by far easier. A large quantity is obtained by bleeding the animal to death by cutting through the large vessels of the neck. The blood is then centrifuged for about 10 minutes and the pure serum, devoid of corpuscles, is used.

One c.c. of the serum is diluted with 10 c.c. of physiological salt solution, that is 10 per cent., and 0.5 c.c. is used for a test. It is $^1/_2$ c.c. that should be taken and not 1 c.c. as done by many.

In order to make the test, take 4 test tubes and mark each by a number or letter, let us say A, B, C, D. I mark them here by letters, because the reagents described above were marked by numbers, so there should be no confusion. We write down the numbers or letters in a notebook, and mark opposite each the reagent we are going to put in. Thus, opposite test tube A, we state: Serum of Mr. Smith to be tested, etc. Then we take a fine pipette, preferably graduated in hundredths of a cubic centimeter, and put into test tube A 0.2 c.c. of patient's serum to be tested; into test tube B we put 0.2 c.c. of the positively syphilitic serum, and into test tube C we put 0.2 c.c. of the positively non-syphilitic serum. Then we add to each of the three test tubes an exactly equal quantity of the antigen described under 3. If the antigen is prepared according to Wassermann's directions, the quantity of it to be added to each test tube is also 0.2 c.c. But the strength of the antigen may vary, and it is best to add the quantity stated in the directions of the laboratory which supplies the reagents. Next we add to each test tube, including also test tube D, which had so far received nothing, 0.5 c.c. of the complement described under 6. Then add to each test tube a little physiological salt solution, so as to bring the quantity in each to about 1 c.c.

The 4 test tubes after gentle shaking are then put for an hour or two into the incubator at 37° C. When there is no incubator, any warm place having about the same temperature will do. But it must not be too warm. At the end of an hour or two hours we add to each of the 4 test tubes 0.2 c.c. of the blood corpuscles described under 4, and an equal quantity of the amboceptor described under 5.

The strength of the amboceptor, however, may also vary, therefore the directions of the particular laboratory must here also be followed.

The pipette must be well blown out, then washed out after each reagent, and when dry the point is passed over a gentle bunsen burner or alcoholic lamp flame. Do not flame a wet pipette, as it will crack.

When all the reagents have been put in, add to each test tube enough physiological salt solution to make up 2 c.c. According to Wassermann the quantity in each test tube must be 2 c.c. and not 5 c.c. as stated in text books. Previous dilution of all the reagents with salt solution, as described by many, simply complicates matters, and is not advisable.

The test tubes are gently shaken up and put away again in a warm place where they can be left *undisturbed* over night. In the morning we look at the test tubes. If test tube D, which contains the so-called hemolytic system, of which we shall say a few words soon, and test tube C, which contains the positively nonsyphilitic serum, contain a clear, red wine-colored fluid without any sediment at all, and test tube B, which has the positively syphilitic serum, contains a yellowish turbid mixture with a sediment, it shows that the reaction has been properly carried out. Then we see what took place in test tube A containing the serum to be tested. If, however, there is *not* a clear red wine-colored solution either in test tube C or D or in both of them, but a yellowish turbid mixture, or if there is a clear red wine-colored solution in test tube B, instead of a yellow turbid mixture, there is something wrong about the reaction, and it is not good.

If, however, the reaction has turned out properly, as said before, then we look at test tube A. If it contains a yellowish turbid mixture, with undissolved blood corpuscles on the bottom, as in test tube B, the reaction is called positive, *i.e.* the patient has syphilis; if, on the contrary, it contains a clear red wine-colored fluid like test tubes C and D, the reaction is said to be negative, *i.e.* the patient has not syphilis.

It may happen, however, that the corpuscles in A are only partially or slightly dissolved as compared with the control test tubes. Call this reaction doubtful and make another examination later. Wassermann ridicules the use of plus and minus signs to indicate the reaction. It is, of course, silly. Now I limited the number of test tubes for the reaction to 4 because Wassermann thinks it is sufficient. There is no necessity to use 6 or 7 test tubes for more controls as recommended by some. This uselessly complicates the matter, especially when one tests several sera at the same time, which is very practical to do. Do not be a greater royalist than the king; do not be more painstaking and accurate than the master himself, for in laboratory work Wassermann is certainly a master.

Now the performing of the Wassermann reaction the way it is described above is a very simple thing. For what can be simpler than putting measured, equal quantities of a few reagents into a few test tubes, put the latter away for an hour in a warm place, then add two more reagents in equal quantities to all of them, then putting them away again and looking at them?

Of course, if you will hear or see the thing described by persons who themselves know very little about it, the matter appears too complicated and difficult. As to the various modifications of the reaction, Wassermann condemns them all, including the Noguchi modification. Indeed, Noguchi's claim

that human blood may contain so many units of amboceptors (the unit-amboceptor in itself is simply an arbitrary unit and is mere guesswork) for the blood corpuscles of a sheep, and that this interferes with the reaction appears to be devoid of foundation. An excess of amboceptors, if it be true that the normal human blood contains them, does not interfere with the reaction. The amboceptor must always be in excess of the blood corpuscles. Thus, before marking the dose of the amboceptor, described under 5, to be taken for the reaction, it is tested. If, for instance, it is found that 0.1 c.c. of amboceptor is the minimum quantity necessary to combine with 0.2 c.c. of blood corpuscles, a double or a triple quantity of the amboceptor is indicated for the reaction, *i.e.* 0.2 or 0.3 of the amboceptor, in order to be sure that all the corpuscles can be combined, otherwise they may remain undissolved and may mislead us. The amboceptor is, of course, invisible, its presence is detected only by the effect it produces by combining with an antigen, like red blood corpuscles. (These are the antigen of the hemolytic system, which will be briefly dealt with immediately.)

We shall now say a few words concerning the theory underlying this reaction. Professor Ficker of the Berlin University once said humorously that it requires a period of incubation before one can grasp that theory. Indeed, at first it appears very hazy and incomprehensible, but after some study and reflection it becomes clear and comprehensible. The principles underlying the Wassermann reaction are those of Ehrlich's side-chain theory and of the deviation of the complement of Bordet and Gengou.

Ehrlich's Side-Chain Theory.—Certain substances when introduced into the animal body, *i.e.* circulation, produce by a reaction, other, opposite, substances. The substances thus introduced are called *antigen*, and those produced in the system are called antibodies. The antibodies thus produced are divided by Ehrlich into three groups. The antibodies of the first group are very simple, those of the second group more complex, and those of the third still more so. Example of antibodies of the first group: When diphtheria bacilli or their toxins are introduced into a susceptible animal they—the toxins—find there in the cells, owing to their peculiar form, bodies or hooks to which they can anchor themselves, and exert their toxic effect. In nonsusceptible animals no such bodies or hooks exist and the toxins remain inert. But in susceptible animals, when the toxins are gradually introduced or are in moderate quantity, more of those bodies are proliferated than the toxins need to combine with. This excess of bodies detach themselves from the cells and float freely in the blood. They are called receptors. When the serum of animals containing those receptors is brought in contact either *in vitro* or *in vivo* with diphtheria toxins (*in vivo* this injection must be made before the toxins get anchored) they combine together; the toxins, in this way, get a hold of an artificial prey, they are satiated, taken up, and cannot combine with or injure the cells of the animal any more. Such as this is diphtheria antitoxin, also tetanus antitoxin. We omit here the discussion of the toxophore and haptophore groups, also intra- and extracellular toxins, as not being material to the subject.

With other microbes the antibody production is unfortunately more complicated and hence the difficulty of producing a good serum with these microbes.

Second Group.—This group consists of antibodies produced in the system by an antigen, which antibodies can combine with it, agglutinate it, or precipitate it. This is illustrated by the agglutination test of Widal in typhoid fever. We shall not dwell on it.

Third Group.—This is the most complicated one and concerns the Wassermann reaction. Certain antigens, like typhoid bacilli or red blood corpuscles from another species, when introduced into the animal do not produce antibodies like the receptors in the case of diphtheria toxins, but they produce antibodies called amboceptors. Whereas the receptors combine easily with the specific toxins that produced them, without any help, the amboceptor combines with the specific antigen only through the intermediary of a third substance called the complement. It must be borne in mind that receptors as well as amboceptors combine only with the particular antigen that produced them and with no other. Thus when red blood corpuscles of a sheep have been injected into a rabbit the amboceptors thus formed will combine only with the corpuscles of a sheep. Furthermore, the amboceptors do not naturally appear in the animal body, but are produced by the introduction of an antigen. The complement, on the other hand, is not a specific production, but exists in the blood of every healthy animal. When the complement alone is needed, it is best obtained from a guinea pig.

The amboceptor is called thermostabile, *i.e.* it is not destroyed by moderate heat, whereas the complement is thermolabile—it is destroyed when exposed to a temperature of 56° C. for half an hour. It also soon deteriorates on keeping.

The fresh serum of an animal containing an amboceptor naturally also contains the complement, for it exists, as we said, in every healthy animal. But when we obtain the serum of an animal containing an amboceptor, the serum of a rabbit for instance, which has been treated with the red blood corpuscles of a sheep—we heat that serum immediately in order to destroy the complement, as it does not keep anyhow, and furthermore we do not know the quantity there is. We obtain better the complement fresh from a guinea pig, when we wish to make the reaction.

The Deviation of the Complement.—When we put into a test tube the red blood corpuscles of a sheep, the serum of a rabbit into which they have been injected, and some fresh serum of a guinea pig containing the complement (this being called the hemolytic system) a combination of the three occurs in the test tube, the corpuscles are dissolved, and there is a clear red solution. If there is no complement added or if the complement is absorbed by another antigen with its corresponding amboceptor, the red corpuscles of the sheep cannot then combine with their corresponding amboceptor contained in the rabbit's serum; the corpuscles are not then dissolved, and there is a turbid yellowish mixture.

Hence the Wassermann reaction. If we bring together the extract of a syphilitic liver (the antigen), with the serum of a syphilitic patient, which naturally contains corresponding amboceptors, and fresh serum from a guinea pig (the complement), there is a union among the three, and the complement is absorbed. When we then add to the same test tube red blood corpuscles from a sheep and the

serum of a rabbit treated with them, *i.e.* their corresponding amboceptors, they cannot unite because there is no more complement, and the corpuscles are not dissolved. If the blood is from a non-syphilitic patient it contains no syphilitic amboceptors, there can be no union with the syphilitic antigen, the complement is not absorbed, then there is union of the hemolytic system, and the corpuscles are dissolved. This is, in short, the idea of the Wassermann reaction.

180 LEXINGTON AVENUE.

THE CONSERVATIVE TREATMENT OF ENLARGED (TUBERCULOUS) GLANDS OF THE NECK.

BY LEO B. MEYER, A.M., M.D.,

NEW YORK.

ASSOCIATE SURGEON, MT. SINAI HOSP.; ASST. VISITING SURGEON, BETH ISRAEL HOSP. AND MONTEFIORE HOME.

THIS paper embodies the conclusions formed as to the best method of treating tuberculous glands of the neck from a careful study of a large number of cases treated by me during the past ten years. It is in no sense controversial. I am well aware from both personal knowledge and from a review of the literature that there are many surgeons who oppose any temporizing in this condition, either because they have seen such poor results from non-operative treatment, or because they consider any tuberculous focus a source of great danger and prefer, when possible, to remove it radically.

At the outset it may be stated that these glands, the scrofulous glands of our fathers, are not invariably tuberculous, though considered so by many. They frequently are simply inflammatory glandular enlargements, such as one finds anywhere in the body in glands which happen to be in the path of lymphatic drainage of an infection.

The condition is extremely common, being found in the majority of children of school age. Several German writers have reported it as existing in 90 per cent. of children between the ages of seven and twelve. The Division of Child Hygiene of the Boston Board of Health in their 1911-1912 survey, reported 13,711 cases of enlarged cervical glands among 118,781 school children, or about 12 per cent. The most important part of this report, however, was the statement that all but 2 per cent. of these subsided without operation.

Before outlining a treatment for any condition it is important to have a clear understanding of the cause; if that cause be an infective agent, not only the character of the agent but the portal of entry is important. In the condition we are considering, the tubercle bacillus is probably the most frequent infective agent, though by no means the invariable one; but whatever the agent, the portal of entry is most commonly the mouth, usually the tonsils or nasopharynx, occasionally the teeth; sometimes all three. While the tonsil usually shows gross evidence of disease, there are many cases in which a buried tonsil that does not look diseased is a constant source of infection. At this point it may be just as well to state that purulent otitis media and a variety of scalp conditions (not forgetting pediculosis) are at times responsible for cervical glandular enlargement, but as they are a relatively infrequent cause, they will not be referred to again. It is of course understood that when present they must receive appropriate treatment.

We all see any number of cases in which there is present either a number of small deforming scars in the neck (the legacy of ruptured or incised gland abscesses) or a large scar due to the more or less complete removal of cervical glands. Frequently under the scar evidence is present of a recurrence of the condition, or what is more probable, of incomplete removal. Most important, however, is the fact that in a very large number of these cases a careful examination of the mouth and nasopharynx reveals enlarged, diseased tonsils or adenoids, or decayed teeth, or all three conditions, evidence of the fact that effects only were treated while the cause was neglected.

It is my opinion that no case of enlarged glands of the neck (tuberculous or otherwise, and in a large percentage of cases a differential diagnosis is impossible without the removal of a specimen) should be operated upon radically, without at the same time, or better previously, correcting all pathological conditions in the mouth and nasopharynx which might act as a source of infection. Unless this procedure is followed, the subject of a thoroughly radical operation is theoretically left without protection against systemic invasion by a cause still active, and if the operation is less radical and only the enlarged and most superficial glands are removed, the remaining glands will almost surely become infected by the original causative agent. The patient is thus worse off than if he had had no operation at all.

In handling these cases it is advisable to increase the patient's resistance against tuberculous infection and to remove the cause of the trouble as far as possible. Long before the surgeon sees them, attempts have usually been made along lines calculated to improve the general condition by giving tonics such as iron and cod-liver oil, and by advice as to diet, hygienic surroundings, life in the open air, etc., and at times by employing tuberculin, usually but not always with benefit; but it is remarkable how often all these measures are taken without any attention being given to a possible cause. In all these patients the first procedure should be the removal of diseased tonsils and adenoids, and the proper treatment of bad teeth, thereby placing the mouth in a thoroughly clean condition; then, if the various hygienic and tonic measures are given a chance, a large majority will never need surgical treatment. Where, however, the process has advanced a little further, and in spite of this routine, some enlarged glands, not yet broken down, remain (and these cases are very few), various methods of treatment applied to the glands themselves should be tried. Among such should be mentioned the injection of 5 per cent. iodoform emulsion in oil or of a 2 to 4 per cent. solution of formalin in glycerin, the use of Bier's hyperemia of tuberculin and more recently of the *x*-ray and high frequency current. Whichever of these methods is employed (and all should be if necessary) there are very few patients who do not respond to treatment satisfactorily and recover without radical operation, provided (and this is of prime importance) we have the cooperation of the patient and there is at his disposal sufficient means to buy proper food and to live under proper hygienic conditions, and sufficient means and time if need be, to spend several months or even a year in the mountains or at the seashore. In other words, for the ideal handling of the condition, after the removal of the cause, we are in the presence of the same problem, though in

a lesser degree, as are those treating pulmonary tuberculosis. But even among the poorest, the complete removal of all possible sources of infection is frequently followed by complete cure.

Those cases seen for the first time after the development of a glandular abscess or after the formation of sinuses due to the opening of these abscesses should be treated with the utmost care, so as to minimize the disfiguring scars which might easily occur. Where only a sinus or sinuses exist, leading down to enlarged glands, the treatment at first is exactly the same as when none are present. Appropriate treatment of the mouth is frequently followed by healing of the sinuses and retrogression of the enlarged glands without any special local treatment. When, however, this does not occur, a little assistance with the curette, stimulation with tincture of iodine, or the use of Beck's paste, together with one or more of the methods suggested, when discussing the treatment of enlarged glands which had not broken down, will usually suffice. Where an abscess exists, the treatment should be extremely conservative. Under no circumstances should it be treated by large incision and drainage. The time for healing under such treatment is interminable, and the scar is unnecessarily large and unsightly. Usually it is advisable to wait until the caseated gland has broken down completely. This, however, is not absolutely necessary and should not be carried to the extreme of permitting the entire side of the neck to become a large abscess. Whenever pus is present, it should be aseptically removed in the same way that we would remove it from a psoas abscess, and after its removal a sterile dressing (preferably wet) to prevent a mixed infection is to be applied. Whether we remove the pus by aspiration, or make a very small incision with a narrow knife and insert a grooved director permitting the pus to flow out, is immaterial. I have obtained good results by both methods with or without a subsequent injection of tincture of iodine. It is important to remember that the process must be repeated every few days until no more secretion is present, and extreme care must be taken not to get a mixed infection. Abscesses treated in this way will heal with pin-point, practically invisible scars. After the abscess is healed, the case is to be handled as is the one that has not progressed so far.

The statement is frequently made that, as these glands are tuberculous, they should be promptly and completely removed, because the patient is in constant danger of a general infection. This statement is inaccurate, for the glands are not always tuberculous. The percentage of enlargements that are tuberculous, as given by different writers, varies from thirty to sixty, and even those that are tuberculous do not necessarily require removal. We do not remove tuberculous bronchial, mesenteric, or retroperitoneal lymph nodes, and yet many patients with these get well. In fact, a large proportion of humanity has a healed glandular tuberculosis somewhere in the body. For the cure of tuberculosis, radical removal is not absolutely necessary, nor is it frequently resorted to even in those cases where its accomplishment is relatively easy. We do not nowadays resect tuberculous joints with quite the same freedom as formerly. It is further not to be forgotten that a radical operation on a tuberculous focus may be followed by a general infection. This is emphasized by Dr. Robert T. Morris, in an article in which is reported the death of a patient from acute general miliary tuberculosis immediately following a radical removal of tuberculous cervical glands.

In conclusion, while I believe in and recommend a more conservative attitude in the treatment of tuberculous glands of the neck, I do not preach a *laissez faire* doctrine. These patients need active treatment, each according to the condition of the glands and his response to the methods employed, which is simply another way of saying that we must individualize and treat patients, not cases.

Some few there are for whom, in spite of everything we do, we cannot accomplish the complete disappearance of these glands. We get improvement up to a certain point only. For these patients an operation is necessary, but only to the extent of removing those glands that are enlarged. The extensive block dissection removing every bit of gland tissue, fat, and fascia in front of, under, and behind the sternocleidomastoid muscle, as if we were dealing with a malignant growth, is unnecessarily harsh, for if we have removed the source of infection in the mouth, those glands in the neck, so slightly involved as not to be enlarged, can be taken care of by the protective bodies of the individual, and need not be removed.

CONTRAINDICATIONS TO THE INTRAABDOMINAL USE OF OIL.

BY WATERS F. BURROWS, M.D.,

NEW YORK.

EXPERIMENTATION with and the further use in abdominal surgery of neutral mineral oil have shown the important, if limited, field where it may be advantageously employed and likewise contraindications to its use. The original animal experiments performed by the writer proved that pure mineral oil could be poured into the peritoneal cavity of a normal animal in large amounts without causing irritation, leading to infection, accumulation of peritoneal fluid, or other deleterious effect, and that it was only slowly and in part taken up and removed by the lymphatics. Upon opening the abdominal cavities of animals thus treated, absence of adhesions was noted and the oil was observed in all parts of the abdomen in a partially emulsified state. Microscopically the oil showed no indications of having caused a peritoneal exudate and there was an obvious absence of leucocytes. With the use of impure oil or in the presence of marked infection, however, the oil became lumpy and thicker, tending to accumulate in various parts of the cavity and to be walled off by adhesions. Microscopically large numbers of leucocytes were then to be seen. It has been shown (Sweet, Chaney, and Willson, *Annals of Surgery*, March, 1913) that these leucocytes have decreased phagocytic action

and thereby lessen the power of the subject to overcome infection.

The writer first used the oil in the human being in a case of acute intestinal obstruction, due to extensive adhesions in the absence of infection. The adhesions were broken up, kinks in the bowel eliminated, and five ounces of liquid petrolatum were left in the abdominal cavity to coat the considerable denuded peritoneal surfaces of the intestines. The results justified the procedure since, although previously fecal vomiting was present, the patient made an uninterrupted recovery without nausea or vomiting, and was entirely relieved of constipation and abdominal distress, which had previously long existed. This led to further studies in the fields of habitual constipation, intestinal stasis, and alimentary toxemia, in which such radical and unnecessary operations as colectomy and intestinal anastomosis or short circuiting of the bowel had been resorted to. In his cases, following division of adhesions, elimination of kinks, and gastropexy or colopexy, as indicated, mineral oil poured into the abdominal cavity proved a safe and valuable adjuvant.

However, since my two former papers upon this subject* did not emphasize the conditions in which oil should not be used, intraabdominally it is necessary, in view of wider use, to recognize fully its contraindications. At the outset it was apparent from animal experimentation that oil was not an aid to the normal defense of the peritoneum in the presence of infection, and by preventing adhesions, and thereby the plastic walling off of infected areas, dissemination of bacteria, if present, would occur. Therefore, the first and most important contraindication to the intraabdominal employment of oil is infection, whether this be present previous to, or occur during operation. After a clean appendectomy or in similar cases where slight soiling of the peritoneum may have occurred, oil may be safely used, but with the amount of infection which necessarily accompanies an intestinal anastomosis it is contraindicated. In gall-bladder surgery, likewise, where a rapid formation of adhesions prevents leakage, oil is positively contraindicated.

Pure, neutral mineral oil, preventing peritoneal adhesions, likewise interferes with the uniting of other tissues to some, but not to the same extent. In the former instance there is a constant movement of the intestinal loops and frequently simply injury, not extensive destruction of the single layer of peritoneal epithelium. However in operations such as cecopexy, gastropexy, sigmoidopexy, hysteripexy, or other precedure demanding firm peritoneal union, oil should not be introduced until the surfaces it is intended should adhere have been carefully placed in contact and sutured.

The use of oil intraabdominally should not be the means for avoiding the after-effects of crude or careless surgery. Rather the careful operator will obviate the necessity for using oil on account of anticipating excessive postoperative adhesions and intestinal stasis resulting from undue peritoneal traumatism by a good technique. However, in those cases demanding operative intervention on account of intestinal adhesions, kinks, angulations, or ptosis, where bowel irregularity, toxemia, nervous and physical debility exist and have resisted medicinal forms of treatment, and where infection is absent, conservative surgery is indicated and oil will frequently be found useful.

In short, it may be stated that infection is the one important and serious contraindication to the intraabdominal use of oil, and moreover that its use under proper conditions is a conservative procedure, which, employed in the unusual case, may obviate the radical operation, today, it would appear, so generally thought necessary.

Medicolegal Notes.

Practising without License — Treatment — Domestic Family Remedies—Chinese Herbs.—The Utah statute against the practice of medicine without a license excepts the sale or administration of "domestic family remedies." In a prosecution for violation of the statute it appeared that the defendant, calling himself a Chinese Herb Doctor, advertising that he could cure all ills, enumerating some, from consumption to pimples, "and any other affliction;" that "Yee Foo Lun, C. H. D.'s ancestors in China for centuries have been famous as expert herbalists, and in addition to his more modern scientific learning he possesses the precious secrets of the curative powers of the Chinese herbs. These secrets are never written, but are handed down from father to son from generation to generation." He asked a patient who called on him what he thought was the matter with him. The patient said he thought he had rheumatism as he had a pain in his shoulder. After feeling his pulse, the defendant told him he was on the verge of a partial paralysis, that he would give him seven treatments a week for $10, and that a cure might be effected in three or four months. A chemist's analysis of the packages given the patient showed in solution a mixture of drugs without definite active principles, but the odor and taste strongly suggested, among other drugs, the presence of ginseng, cinnamon, licorice, sarsaparilla, etc. The defendant testified that he did not diagnose diseases, but asked the patient what the last doctor who had treated him said he had and treated him for that, or asked him what he thought he had himself; that the packages sold to the patient contained about fourteen different kinds of herbs, most of which grew only in China, could be obtained only in a Chinese store in San Francisco, and he could tell their names only by reference to a catalogue in Latin, Chinese, and English. He contended that they were domestic family remedies. It was held that the concoction could neither in law nor in fact be regarded as a domestic family remedy. The fact that it was harmless was not a controlling factor. "Such a compound or concoction," said the court, "is not something commonly kept by unprofessional persons in their homes, or of which they have general knowledge. Instead of calling it a domestic family remedy, it is better to call it by its right name—a subterfuge to deceive the credulous and the afflicted. When the question is looked at from the defendant's evidence the matter is still worse. A mixture of fourteen different herbs, equally efficacious for rheumatism, paralysis, appendicitis, piles and pimples, and which are so well known that to properly name and describe them requires the use of three languages; their curative power so familiar as to be understood only by Chinese expert herbalists, who acquired knowledge "of the precious secrets" only through tradition and by scientific learning so modern as to have been handed down generation after generation by Chinese herbalists and ancestors of the defendant, and which are so general and so common as to be had only at a Chinese store in San Francisco, or at a Chinese Institute conducted by a Chinese Expert Herbalist, can in no sense be regarded as a domestic family remedy. It is anything but that."

It was also held that his claim that he charged only for the herbs and nothing for diagnosis, consultation, or treatment was, like his concoction, a mere pretense, and an attempt to exculpate himself by bookkeeping. As well say any one charged nothing for an operation, but charged $100 only for bandages and antiseptics. The conviction was sustained.—State v. Yee Foo Lun, Utah Supreme Court, 147 Vac. 488.

THE SITTING POSTURE IN THE TREATMENT OF PNEUMONIA.

THIS unusual method was proposed over one year ago by C. Widmer of Zofingen, Switzerland, on the basis of the good results obtained thereby in the treatment of over fifty patients in whom the nervous symptoms were particularly pronounced. The method consists in sitting the patient up on a couch for from four to six hours daily after the prostrating effects of the initial chill have worn off and before the onset of delirium. This mode of treatment is said to be adapted for young subjects, for alcoholics, and also for those in whom the condition of the heart may cause some concern. The results of the treatment are said to be a lowering of the temperature, a diminution in the frequency of respiration and of the heart beat, an increase in blood pressure, and a general improvement in the sense of well being.

Mlle. E. Cottin has essayed this method in the Medical Clinic of Professor Bard of Geneva and reports her results in the *Revue Médicale de la Suisse Romande*, May 20, 1915. She chose twenty patients among those severely ill, the youngest being 20 and the oldest 80 years of age. The treatment was instituted one to several days after their admission to the hospital, their temperature at the time being in the neighborhood of 40 deg. C. Generally in the afternoon they were taken from bed, clad in a dressing gown, and seated on a couch near the bed. All of the patients stated that they felt better when sitting up; their respiration was less labored, the sputum was brought up with greater ease, and the sweating was less profuse. The objective sign showed a slighter degree of cyanosis, a diminution in the frequency and amplitude of the respiratory movements, and a slowing of the heart to the extent of ten to twenty pulsations. The temperature dropped several tenths of a degree, and in one instance, one degree and a half C., following the assumption of the sitting posture. In no instance was weakness of the heart or any other weakness observed.

The rationale of this treatment, as explained by Mlle. Cottin, is a simple one. The sitting posture relieves the pulmonary circulation and the right heart by causing a large volume of blood to accumulate in the veins of the lower extremities, the effect being the same as that of a copious venesection. Moreover, the movements of the diaphragm are facilitated by the sitting posture, percussion of the healthy side of the chest showing that this posture enables the lung to expand in the downward direction to the extent of three and a half centimeters greater than the recumbent posture.

SPINA BIFIDA.

DR. H. H. TROUT reports in *Surgery, Gynecology, and Obstetrics* for May, 1915, a case that is most interesting and instructive and one which may possibly mark the beginning of a new era in the treatment of this unfortunate malformation.

The patient was a girl, eight months of age, and said to be practically normal except for a rather large spina bifida in the lumbosacral region, although the reflexes, trophic changes, etc., were uncertain and the lower extremities were so weak that the baby moved them infrequently and then only slightly. The age and weakness of the child made it almost impossible to ascertain correctly concerning sphincter control. The defect was closed with a bone graft from the tibia of the father. The technique of operation was as follows: An incision was made over the crest of the father's tibia and a rectangular piece of bone about 6 cm. long, 4 cm. wide, and 2 mm. thick was removed with its periosteum and placed in warm saline solution until the field for implantation was prepared. After the child was etherized, a transverse elliptical incision was made over the tumor, the sac was exposed, and the dissection was quickly carried down to the spinal cleft. This cleft was found to be about 2 cm. wide and 5 cm. long. An opening was then made in the fundus of the tumor, allowing about 300 c.c. of clear fluid to escape. This exposure showed the various nerve elements radiating over most of the sac, especially on its dorsomedian aspect. Since every attempt to dissect the nerve elements free was accompanied by alarming reflex symptoms, the sac was simply sutured with plain catgut and was tucked into the cleft. The bone graft was then anchored over it by chromic sutures. These sutures were passed through the periosteum of the graft, the cartilage of the transverse and spinous processes, and any other firm structures that the curved needle would grasp. In order to prevent too much pressure on the collapsed sac the graft was bent like a bow and held in this position by the sutures. A Roentgen picture, four months later, showed rather extensive bone growth and the clinical result was extremely satisfactory.

In a search of over 400 case reports in the Surgeon General's Library, Trout failed to find any case similarly treated; and from his experience in this case he is convinced that the method is safer, quicker, and simpler than any other type of spina bifida operation that has been employed, and he believes it worthy of further trial in those cases not associated with hydrocephalus. In selected cases, and with proper modifications in the technique to suit the individual case, it is reasonable to believe that the use of the bone graft taken from the father or mother of the child will give a far larger per-

centage of satisfactory results than has been possible with the older methods of handling these spinal defects.

STRAW MEAL AS FOOD.

When this subject was originally mentioned in the daily press, there was a corresponding dearth of information thereon in medical periodicals, and the little which did appear savored of ridicule, since it had long been taught that straw was practically without nutrient value as far as mankind is concerned. There is, however, plenty of evidence that cows can be fed through the winter almost wholly on oat straw and at the same time give good milk. Certain old beliefs that straw is in one or another way dangerous as food have also been shown to be false. In famine times barks, sawdust, etc., have been of use as food, although it has been assumed that their action was a purely mechanical one, bringing about a blunting of the hunger sensations by filling the stomach.

These and many other facts were brought out by Friedenthal at a military medical evening held last spring (*Berliner klinische Wochenschrift*, April 26). This author, at first skeptical, tested a straw meal diet on himself. The meal was baked into bread, and when oat straw was used the latter was more palatable than ordinary war bread. The milling was purposely coarse, as the writer wished to test its utilizability *per se*. The nutrient value was small, but there was no sign of intestinal irritation. An addition of 33 per cent of straw meal to war bread greatly improved the latter in looks and palatability. The nutrient value is, therefore, not wholly material. A palatable, digestible, and nutritious bread can be eaten in any desirable quantity. As straw meal can be supplied in practically unlimited quantities thousands of tons of potatoes can thereby be released for separate consumption, the potato addition in war bread having proved unsatisfactory in several respects.

Agglutination in Syphilis.

It is something over two years since we had occasion to call attention to the work of Touraine, who demonstrated a specific agglutination when the serum of a syphilitic was brought into contact with a number of spirochetes. At that time the difficulties of the work were very great. He obtained his organisms from condylomata and experienced much trouble in the endeavor to free them from the serum of the donor, nevertheless he obtained a high percentage of positive reactions in syphilitic patients. At that time it was said that the work was merely of scientific interest. In the interval, however, the *Treponoma pallidum* has been located and grown in pure culture and the use of laboratory animals has been worked out. In consequence, Zinsser and Hopkins (*Jour. Exper. Med.*, 1915, xxi, 576) have been performing agglutinations with pure spirochetal emulsions and the serum of rabbits inoculated with the organism. They observed the mixtures both microscopically and macroscopically and obtained positive reactions in dilutions as high as 1:2000. The work is obviously of great importance. The reaction may come to be of diagnostic value and theoretically would have many advantages over the Wassermann reaction. Almost certainly it will be of much aid in the identification of spirochetes. But perhaps the most important factor of the work is that it is "a demonstration of definite antibodies in the circulation of animals treated with dead emulsions of *Treponema pallidum*." The work will be continued, we hope, in the endeavor to see whether the serum of syphilitic human beings contains sufficient antibodies to make the reaction of practical value in diagnosis and the results will be awaited with interest.

Latent Malaria and Typhoid Immunization.

The claim has been made that patients with the *Plasmodium malariæ* in the blood who contract another infection sustain a disappearance of these organisms from the circulation. On the other hand, practitioners in malaria-ridden countries assert that in latent malaria a superinfection with another disease (variola, etc.) will cause an outbreak of intermittent fever. These examples of antibiosis and symbiosis do not appear calculated to discredit each other, since analogies exist in this respect in other diseases. At a meeting of the Royal Imperial Medical Society of Vienna last February (*Berliner klinische Wochenschrift*, April 19) Schlesinger reported the case of a soldier who had gone through an affection of doubtful character, resembling alike typhoid fever and malaria. The specific tests were all negative. The diagnosis was malaria. Ten days after defervescence the patient received an antityphoid inoculation and on the next day developed a pronounced tertian ague, plasmodia now being present in the blood in abundance. The malaria yielded to quinine and cacodylic acid. In this case an obscure atypical malarial affection was rendered typical by the inoculation.

News of the Week.

Committee of American Physicians for the Aid of the Belgian Profession.—Dr. F. F. Simpson, treasurer, 7048 Jenkins Arcade Building, Pittsburgh, Pa., reports the following contributions for the week ending July 3, 1915:

Stamford Medical Association, Stamford, Conn.	$25.00
Buchanan County Medical Society, St. Joseph, Mo.	27.34
Capt. W. H. Allen, M.C., U.S.A., Manila, P. I.	10.00
Yakima County Medical Society, North Yakima, Wash.	25.00
Receipts for the week ending July 3	$87.34
Previously reported receipts	7,457.00
Total receipts	$7,544.34

A New Health Commissioner for New York.—Dr. Goldwater, health commissioner of New York City, recently resigned in order to be able to resume his duties as superintendent of Mt. Sinai Hospital, and Mayor Mitchel is said to be considering several men who have been suggested to succeed him. One of them, it is announced, is Dr. W. C. Woodward, Health Commissioner of the District of Columbia, and several others are New Yorkers. Dr. Woodward has shown himself to be a very efficient officer and would no doubt do excellent work, but there are also a number of men now in the department who are fully competent and would make most capable commissioners. The promotion of one of them would seem to be more in accordance with civil service ideas.

A Doctorate of Public Health.—In accordance with a recent recommendation of the Public Health Council of the State of New York, the University

Bellevue Hospital Medical School on July 15 will open a series of courses in public health and sanitation, leading to a new degree—Doctor of Public Health. It was suggested by the Health Council that the medical schools of New York State provide courses in sanitary science in order that health officers might receive a training which would emphasize the prevention of disease rather than merely its control. Two courses will be offered. The first of these is the six week summer course, not leading to a degree, but which may be included in the second course of training, which gives the degree of Doctor of Public Health, and which extends over a period of two years. Candidates for the degree will be required to devote the first year to lecture and laboratory work, while the second year's work will consist in the preparation of a thesis on some special problem in public health. There is also the option of substituting for the shorter course a correspondence course culminating in a week of laboratory work.

Health of the Canal Zone.—The report of the health officer of the Panama Canal Zone for April states that the total number of deaths from all causes among the employees for the week was 8; of these five deaths were from disease, giving a ratio of 1.76 per thousand, as compared with 4.91 for the preceding month, and 5.53 for the corresponding month last year. The total population of the Canal Zone is 33,652, among whom there were 18 deaths; of these 16 deaths were from disease, giving a rate of 5.71 per thousand, as compared with 8.23 for the preceding month, and 11.10 for the corresponding month of last year. Of the total deaths from disease the percentage under 5 years was 69, compared with 52 in March.

The New York City Death Rate.—There were 1277 deaths and a death rate of 11.47 per thousand of the population reported during the week ending June 26 as against 1258 deaths and a rate of 11.75 in the corresponding week in 1914, an increase in the absolute number of deaths of 19 and a decrease in the rate of .28 of a point, which is equivalent to a relative decrease of 31 deaths. The only noteworthy feature of the week's mortality was the increase in the deaths from measles and bronchopneumonia. The death rate for the first twenty-six weeks of 1915 was 14.21 per thousand against the rate of 14.79 during the corresponding period of 1914, a decrease of .58 of a point.

Falling Birth Rate in Paris.—So far from there being a large output of war babies, as was predicted, the decline in the birth-rate in Paris since the beginning of the war has been very noticeable. The rate in 1914 averaged 1000 births daily, but at the beginning of 1915 the figures dropped to 850 and there has been a rapid decline since then. In the week ended June 12, the last week recorded, there were only 356 births.

Medical Library Association.—At the recent annual meeting of this association, the secretary reported that there were now 51 library members, of which 3 had joined in the last year; 44 individual members, of whom 8 had joined in the last year. Thirty-eight libraries and 41 individuals had paid for 1915. There is one library member in arrears for 1914 and under suspension. Four individual members have resigned. The association has been in existence for eighteen years and has filled a unique place among medical libraries. The work is largely altruistic, as libraries interested do all in their power to help each other. The membership fees are small and expenses are kept at the lowest possible amount consistent with the service rendered. The treasurer's report shows a substantial balance which will allow a broadening out of the work this year. The president of the association is Lieut.-Col. C. C. McCulloch, Jr., the secretary and treasurer, Dr. John Ruhräh, 1211 Cathedral street, Baltimore, Md.

Revolt at the Montefiore Home.—It is stated that 100 patients left the Montefiore Sanitarium for indigent tuberculous patients at Bedford a week or two ago because they were dissatisfied with a change in the officers of the institution which had recently been made, and with the promulgation of somewhat more stringent rules regarding absence from the sanitarium without leave.

The Bellevue Administration Praised.—The administration of Bellevue and Allied Hospitals, New York, is praised for economy in a report recently made to the Comptroller by R. B. McIntyre, chief examiner of the bureau of municipal investigation and statistics in the Finance Department. The daily cost per patient, $2.13 in the year 1913, was decreased to $1.99 in 1914. The average cost per patient for the past ten years is $2.02. The report says: "It must be conceded that the financial showing of Bellevue and Allied Hospitals for 1914 as compared with 1913 is very creditable to it; for despite the various items of increase developed by our analysis of its expense reports the fact remains that with an increase in patient days from 656,949 to 717,604, or approximately 9 per cent., the expenses of the department only increased from $1,399,142.24 to $1,431,443.66, or but about 2.3 per cent."

Dr. Frederick Tilney of Brooklyn has been appointed professor of neurology at Columbia University, succeeding Dr. M. Allen Starr recently resigned.

Professor Metchnikoff's Seventieth Birthway was lately celebrated very quietly at the Institute Pasteur. MM. Darboux and Roux, speaking respectively as representatives of the Institute of France and the Pasteur Institute, reviewed the work done by the Russian scientist. By way of reply, Professor Metchnikoff delivered an interesting address on the prolongation of life. The publication of a "Festschrift" which had been planned in his honor was necessarily abandoned.

Dr. David K. Henderson, resident physician at the Phipps Clinic of the Johns Hopkins Hospital, has resigned to accept the superintendency of the Royal Asylum of Scotland at Glasgow. Dr. Roscoe W. Hall succeeds him at the Phipps Clinic.

Dr. Moyer S. Fleisher has been appointed assistant professor of bacteriology at the St. Louis University School of Medicine.

A Good Roads Movement Among Physicians.—The Ohio County (Ky.) Medical Society organized a good roads club at a meeting held July 2.

American Medical Association Medals.—The committee on awards for scientific exhibits at the San Francisco meeting granted gold medals to the pathological departments of Stanford University and of the University of Michigan; to the Indiana State Board of Health, for its exhibit on a public health campaign; to Drs. C. C. Bass and F. M. Johns of Tulane University for their exhibit on pyorrhea alveolaris and malaria; to Drs. Claud A. Smith and J. Witherspoon, on hookworm; to the pathological laboratory of the New York Lying-in Hospital, on the demonstration of the cultivation of human tissue *in vitro;* to Dr. Martin H. Fischer of Cincin-

nati, on newer experiments in the physiology and pathology of kidney functions, and to Dr. J. T. Case of Battle Creek on lantern slides illustrating Roentgen-ray studies.

Medical Assistant, District Attorney's Office, New York City.—The New York State Civil Service Commission announces an examination on July 31 for an appointment to this position at a salary of $5,000 per annum. The duties of the position "include the examination of the dead body and of the premises where it is found for the purpose of ascertaining all facts which will aid in the elucidation of the time of and circumstances surrounding the death; the ascertainment by autopsy of such facts as may be shown relative to the cause of death; the examination of all material obtained from the body by laboratory means; assistance to the district attorney in the preparation of the case for trial; testimony as a medical witness not only as to all questions of facts as mentioned above, but also by reason of actual experience as an expert on medical subjects. The qualifications required for the position therefore are experience in the clinical branches of medicine and surgery, the accurate observation of the dead human body in regard to all facts connected with the cause of death, and the changes that take place in the dead body following death; experience in the use of laboratory means, namely, the microscope, the spectroscope, bacteriological, chemical, and serological analysis for the purpose of proving the cause of death, and the use of these methods in the examination of exhibits for the purpose of elucidating the necessary facts in connection with medical matters in assisting the district attorney in the administration of the criminal law. This necessitates that the appointee have experience including the whole subject of medical jurisprudence and such scientific subjects as are connected therewith, as clinical medicine and surgery, pathology, pathological anatomy, pathological histology, bacteriology, chemistry, serology in connection with the use of the preciptin test for the identification of human blood stains, and toxicology so far as the necessary methods of procedure are concerned; the practical work of isolation of poison is a special branch, which, with his many other duties, the medical assistant could hardly be called upon to perform. No written examination will be given, but candidates will be rated on education and experience in connection with matters indicated above. An oral examination may be held. Candidates should be particular to give full details of their experience in answer to question 20 on the application blank. Open to residents of New York County only." An application blank may be obtained by addressing the State Civil Service Commission, Albany, N. Y.

Fire in the University and Bellevue Hospital Medical College.—A fire that started from unknown causes in the basement of the college building on the evening of Wednesday, June 30, did about $2,500 damage to the building and equipment.

The "Hospital News," a magazine for hospital workers, now in its fourth year of publication, has recently been acquired by a number of physicians in Washington. The editors-in-chief are Drs. Wilfred M. Barton and Walter A. Wells, assisted by twenty-one associate editors.

Obituary Notes.—Dr. HARRY GRAY of Greenwich, Conn., died on June 19 after a long illness. He was born in Cambridge, N. Y., in 1842 and was graduated from the College of Physicians and Surgeons in this city. He came of a long line of medical practitioners, his great-grandfather having been a surgeon in the War of the Revolution.

Dr. SERAPH FRISSELL of Hinsdale, Mass., died in Dalton on June 20 at the age of 74 years. She was graduated in medicine from the University of Michigan in 1875 and began practice almost immediately in Pittsfield. She was the first woman admitted to membership in the Berkshire County (Mass.) Medical Society.

Dr. CHARLES A. MEINE died at his home in Germania, Pa., on June 7 at the age of 85 years. He was a graduate in medicine of the University of Marburg.

Dr. ALFRED MITCHELL, professor emeritus of internal medicine at the Medical School of Maine, died at his home in Brunswick on June 13, at the age of 77 years. He was a graduate of the College of Physicians and Surgeons, New York, in 1865. He was associated with the Maine Medical School nearly his entire professional life, having been appointed lecturer on pathology in 1869 and resigning with the title of professor emeritus in 1911. He was dean of the faculty from 1898 to 1911. He left four children, one of them, Dr. Alfred Mitchell, Jr., a physician of Portland.

Dr. LEON L. FRIEDRICH died at his home in Washington, D. C., on June 15 after a long illness. He was born in Washington in 1858 and was graduated in medicine from the George Washington University in 1881.

Dr. ORIN H. STUTSON of Columbus, Ohio, died June 12 of acute tuberculosis. He was born in Obz Junction and was graduated from the Starling Medical College in 1898.

Dr. WILLIAM G. HALL, formerly a practising physician in Jefferson, Mo., died at the home of his son in Kansas City on June 11 at the age of 84 years.

Correspondence.

FROM DR. DEPAGE.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR: I enclose herewith the translation of a letter which I have just received from Dr. Depage, and which he wishes to have published, in acknowledgment of the many letters which he has received from America since the tragic death of Madame Depage on the *Lusitania*.

R. H. HARTE, M.D.

PHILADELPHIA, June 30, 1915.

My dear Colleagues: I have received from a large number of you, and notably from the committees which you have formed, the most touching tributes of sympathy and of condolence for the catastrophe of the *Lusitania* in which my wife lost her life. These tributes are so numerous and so unanimous, that I wish to express to you publicly my appreciation of them. I address myself to you, my dear Colleagues, as the authorized representatives of the humanitarian sentiments which so honor the great American Nation.

You all know, as I wrote to you when my wife left for America, for what purpose she accepted the mission which the Red Cross confided to her. In the presence of the unexampled miseries of which we have been the prey, she had resolved to solicit your fraternal assistance. You gave her that largely, I should say "joyously" if the word could be pronounced in these times.

The letters my wife wrote to me in the course of her mission told me how you worked for her and revealed to me the extent and generosity of your projects for our wounded. Your hearts were open to our appeal; your country did not delay in coming to our assistance. Powerful America wished to take under her

protection our little people, tortured but always valiant.

My great sorrow does not permit me to reply as I wish I might to each one of you. Only to-day have I been able to measure—thanks to the letter of your compatriot, Dr. Houghton—the extent of the gratitude I owe, to him first for having risked his life in trying to save that of my wife, and after that to you all for your devoted help in our common work.

Under the strain of my emotion, the sentiment of thankfulness is the only one to which at this moment I am able to give expression. Permit me to do so with all my heart.

A DISCLAIMER FROM THE POLYCLINIC HOSPITAL.

To the Editor of the Medical Record:

Sir: In view of the publicity which has been given by the lay press to a method of treating inoperable cancer, and the use that has been made of the name of the Polyclinic Hospital therewith, the management of the Polyclinic desires to disclaim any connection with or responsibility for this method of treatment. The cases that have been treated in the hospital have been received as the private cases of physicians who have the privilege of sending patients to the pay wards and private rooms of the hospital.

Board of Management,
Polyclinic Hospital.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

HOSPITAL SUNDAY—NEW FUND FOR SICK AND WOUNDED—LISTER INSTITUTE—ANTITOXINS—RESEARCH—OBITUARY.

London, June 18, 1915.

The week opened with Hospital Sunday, which was observed in practically every church. In most of the pulpits special claims were urged for the year as one of exceptional strain. The King sent to the Lord Mayor a check for £100 on behalf of the fund. At St. Paul's Cathedral Canon Alexander pleaded with his hearers that the glamor of temporary help should not blind them to the permanent needs of these institutions.

At Westminster Abbey Canon Wilberforce declared that in having all that was best in medical aid at the disposal of thousands of our wounded soldiers the army had been increased by a full army corps.

At the Temple Church Bishop Carpenter said the need was increased by the strain and stress of the war, but so far the contributions had not risen, though the cost of food, drugs, and necessities had. He hoped their liberality would meet the case.

The King's Hospital Fund has the same object and pursues the same course toward its attainment as the Sunday Fund, and the efforts of both in support of our 126 hospitals and other allied institutions need to be supplemented by further voluntary contributions to carry on the work, for their small income from capital is altogether inadequate to meet the continual cost.

On Wednesday a New Mansion House Fund for the sick and wounded in the war was founded at a public meeting presided over by the Lord Mayor (Sir Ch. Johnston). It is to be administered by the Red Cross Society and the Order of St. John of Jerusalem. What was asked, said the Lord Mayor, was that the city of London should make a united effort worthy of its fame and of the cause by coming to the support of this fund for the British Red Cross and the Order of St. John. Mr. Asquith telegraphed to testify from his experience of the admirable work of these two organizations. Mr. Balfour wrote that pressure of public business prevented his presence, though expressing the warmest sympathy with the great object of the meeting. He felt nothing could appeal to the patriotism and humanity of the city more strongly than the great societies which have done so much for those who have suffered in their country's cause. Lord Lansdowne came as the successor of Lord Rothschild in the chairmanship of the Red Cross. He said that on the day of his death Lord Rothschild sent a message to the Red Cross Society showing his deep interest in the present meeting. The society was initiated by Lord Wantage, who also founded the National Aid Society for Sick and Wounded. The Order of St. John was ancient—went back to the eleventh century. The two were in close touch and at the outbreak of war formed a joint committee, and the magnitude of their task like that of the war was appalling to one's idea of humanity or civilization. Three-quarters of a million of our men at the front! and the Prime Minister stated a day or two ago that something like a quarter of a million casualties had been suffered by the British forces. They had been most fortunate in the medical department, and the best relations existed between the voluntary societies and the official surgeons. They were proud of the R. A. M. C. and ready to help in every class of their work. An agency had been established for tracing the missing, following up every clue towards their restoration to their friends. Funds had been sent from the dominions besides shiploads of stores. In closing Lord Lansdowne announced the receipt of a letter containing a check for £20,000 from Mr. Waldorf Astor—the second of this amount from that gentleman for the Red Cross.

Mr. A. Stanley, chairman of the Joint War Committee, referred to the memoir of Lord Wantage, who said however well organized an army medical service might be it never had and never would be able to cope adequately with emergencies of a sudden war over a large scale. Voluntary organizations were necessary auxiliaries. As evidence of the practical work of the joint committee, Mr. Stanley mentioned two incidents within his own knowledge. 1. Just before closing time, 6.30, one evening an order came for no less than 20,000 articles of different kinds, such as tooth brushes, etc., for immediate delivery; they were delivered the next morning. 2. One Sunday they were told that a hospital was urgently required for Calais as soon as possible. At 5.30 p. m. that same Sunday evening a special train left Victoria carrying the full personnel for a hospital of 120 beds together with a large amount of stores, two or three motors and two or three ambulances. That, his lordship claimed, proved the effective co-operation of the R. A. M. C. and the Joint Committee. Sir R. Hudson, chairman of the Finance Committee, gave some important and encouraging facts. Contributions were received on the first day amounting to the goodly sum of £87,455.

The Lister Institute has rendered the greatest service during the war to both the army and navy medical departments. At the outbreak of the conflict an ample supply of serums was provided at cost price, entailing no little extra work in the laboratories. This was eagerly engaged in by the staff and outside experts have been constantly ready to

afford any assistance that might be needed. Up to the end of March, besides numerous prophylactic preparations made and delivered wherever required, the army and navy have been supplied with 120,640 doses of tetanus antitoxin, 18,500 doses of diphtheria antitoxin, and 770,000 doses of antityphoid vaccine. The department of experimental pathology sent to the front in October Mr. S. Rowland, assistant to Dr. C. J. Martin, with the first mobile field battery. This was found so useful in the early diagnosis of infectious fevers and in the detection of carriers that three others were forwarded on request of the medical officers. The institute has been giving great assistance to the medical service in other ways. Its staff have fitted up and arranged laboratories and supplied medical officers and bacteriologists to hospitals. These, in conjunction with the Canadian staff, made a bacteriological examination of the throats of over 1400 men, among whom they detected and isolated thirty carriers. Afterwards Dr. Penfold of the institute, together with Dr. Johnston of the L. G. B. and Dr. Fison, Medical Health Officer for Salisbury, made a similar investigation into an outbreak in that city. This resulted in their finding that the serums available at the time were not effectual. Accordingly the institute set to work to immunize horses as rapidly as possible with strains of the organism from cases occurring in this outbreak. Drs. Ledingham, Penfold, and Hartley have been appointed pathologists to the new King George Hospital. Dr. Atkin and Mr. Greenwood (statistician to the institute) have been nominated in response to a request of the Royal Society to make an inquiry into swine fever. The report of the institute mentions that the exigencies of the war have greatly depleted its staff. But though this has thrown extra work on those remaining at headquarters they have been able to meet the demands of the army and navy without diminishing their other investigations.

You may remember that from time to time there has been some talk of amalgamating the institute and the Medical Research Committee. The proposal was disapproved at a meeting of members last November, although it was brought forward by the governing body, which still hopes the question may be reconsidered later on—say, after the war. The report closes with a handsome tribute to the director and his staff.

Surgeon-General George William Robertson Hay, I. M. S., died on the 26th ult. He qualified in Edinburgh in 1867 and took the M.D. there the next year, at once entering the Indian service as assistant surgeon. Passing through the several grades of the service, he reached the surgeon-generalcy in 1900 and retired at the close of 1904 as the P. M. O. Madras.

Deputy Surgeon-General Hy. Joseph Rose has died at the age of 82. He qualified at the Dublin College of Surgeons in 1855, joined the army medical department the same year and saw service in the Crimea, receiving the medal with Sebastapol clasp, also the Turkish medal. He served in the China war of 1860, for which he was awarded the medal with two clasps. In the Afghan war of 1878-80 he also obtained the medal. He retired in 1881.

Dr. Geo. Moore, late of Torquay, has died there in his 84th year. He graduated M.D., St. Andrews, in 1862, and had been for fifteen years medical superintendent at Jersey Lunatic Asylum. He was also Medical Health Officer for Hartlepool and honorary physician to the hospital.

OUR BERLIN LETTER.

(From Our Regular Correspondent.)

CONGRESS OF GERMAN MILITARY SURGEONS—SACRIFICES OF THE MEDICAL CORPS—SURGICAL INDICATIONS AT AND BEHIND THE FRONT—WOUND INFECTION—GUNSHOT WOUNDS OF THE SKULL—WOUNDS OF THE CHEST—ABDOMINAL WOUNDS—PROJECTILE FRACTURES OF THE ARM AND LEG, WOUNDS AND INFECTIONS OF JOINTS—SURGERY OF THE BLOOD VESSELS, ANEURYSMS.

BERLIN, May 15, 1915.

THE annual congresses that are usually held in Germany about Easter have, of course, been omitted this year. Nevertheless, in these trying days there has still been the opportunity of holding a surgical congress at which the newer problems presented by the war have been discussed. On April 7 about 1,000 military surgeons met at Brussels. They came from all parts of the army. This fact alone that so many medical officers could be spared should convince skeptical outsiders that conditions in Germany are not particularly bad. Yet the war has brought home to us the fact that others will not believe us. In combating this incredulity logic is futile.

The work of the congress cannot be described better than in the words of the motto of the sanitary corps: "The head for science! The heart for the army! The blood for king and country!" In fact, an almost incredible amount of scientific work has been accomplished in spite of the unfavorable outward circumstances. Above all, the striving has been to give to every soldier the best of medical aid possible at any time. That this ideal has involved unusual personal sacrifice is indicated by the large mortality of the medical officers of the army.

The presiding officers, the speakers, and those who took part in the discussions at the congress were those to whom we have been accustomed in years past. Indeed, with eyes closed we would have imagined ourselves in the Langenbeck Hall in Berlin. The light of day fell upon the gray service uniforms of the officers and upon the city of Brussels—and this ended the illusion. Space permits only a reference to the topics that came up for discussion and a brief summary of the important points presented.

The Indications for Surgical Treatment at and Behind the Front: Hemostasis; Transfusion.—Angerer presided and Garré opened the discussion. He said that in the presence of arterial bleeding the artery clamp should be applied to the injured vessel and should be left in place, being included in the dressings. Autotransfusion and the use of stimulants are superior to saline infusions in the treatment of the acute anemia following hemorrhage. Tangential wounds of the skull and intracranial hematomata require trephining as soon as possible. In gunshot wounds of the neck free use of morphine usually obviates the performance of tracheotomy. In open pneumothorax prompt operation is necessary. In the management of gunshot wounds of the abdomen one must distinguish between the following: If there is internal hemorrhage immediate operation is demanded; if there are wounds of the intestine operation should be attempted only if this is possible within the first 12 hours. In shrapnel wounds the parts should be freely laid open, carefully examined and sponged dry and all recesses should be carefully drained.

Wound Infection, Particularly Tetanus and Gas

Gangrene.—Korte presided and Kümmel opened the discussion. He said that tetanus is more prevalent in this war than in former wars, constituting 6.5 per thousand cases as against 3.5 per thousand in 1870. If the incubation period is very short the mortality is 100 per cent; if the incubation period is 7 days the mortality is 90 per cent; if 7 to 14 days, the mortality is 50 per cent; if 14 to 20 days, the mortality is 30 per cent. An early symptom is difficulty in swallowing. The results of prophylactic inoculation with 20 antitoxic units are good. The antitoxic treatment is effective only in the mildest cases, and then with the use of massive doses only. Magnesium sulphate has been most serviceable in chronic cases, but so also have the usual narcotics in large doses. Of great value also are prolonged baths. Gas gangrene is common but erysipelas is rare. In the former the bacillus of Fraenkel is easily and frequently found. The mortality is 33 per cent. Until the onset of gangrene deep incisions down to the fascia are indicated. Also if the gangrene extends only down to the fascia the incisions suffice. Similarly in cases without general infection amputation may thus be avoided.

Gunshot Wounds of the Skull.—Müller presided and Tilmann and Enderlen opened the discussion. Tilmann said that the operative treatment of gunshot wounds of the skull is to be carefully undertaken, and then only by experienced surgeons and under aseptic conditions. That wounds in which the projectile has completely traversed the skull frequently heal without any farther intervention. Tangential shot wounds should be operated upon. Splinters of bone can often be detected by the finger. Wounds resulting from rebounding bullets are also to be opened. In meningitis lumbar puncture should be performed. In encephalitis, in spite of the doubtful prognosis, an abscess should be sought for and if found emptied. Enderlen said that every wound of the skull should be examined with the *x*-ray. Only superficially-lying projectiles should be removed immediately. Further operation is permissible only if the patient can be kept in one place for four weeks. Plastic operations in the dura and skull should be avoided. Of the author's 311 cases of gunshot wounds of the skull 149 died.

Wounds of the Chest.—Garré presided at this symposium, which was opened by Sauerbruch and Borchardt. The former said that among 22,145 wounded there were 836 instances of projectile wound of the chest, of course not counting the dead upon the battlefield. Gunshot wounds of the chest wall are harmless, but shrapnel wounds are more unfavorable and are to be treated very carefully. In these it is often necessary to suture the lung. In projectile wounds of the lung secondary hemorrhage and infection frequently occur as late as the third or fourth week. Indeed, infection from the lungs plays the greatest rôle in these cases. The mortality is 12 per cent, but with fractured ribs and foreign bodies in addition to wounds of the lung the mortality is 24 per cent. Frequently a second rise of temperature on the sixth or seventh day is an indication of inflammation and not of resorption. If there is an infected hemothorax the indication for treatment is aspiration and not resection of rib. In shrapnel wounds of the lung the prognosis is bad. Borchardt stated that of the fatal cases 5 per cent were to be attributed to hemorrhage and over 60 per cent to infection. If the hemothorax does not diminish in eight or nine days aspiration is indicated. The wounded should not be transported before the end of fourteen days and preferably not before the end of three or four weeks.

Wounds of the Abdomen.—Kümmell presided and Körte and Schmieden opened the discussion. Körte reported the results in 312 cases, of which 38 died at the clearing hospital and 146 in the base hospital —a total of 53 per cent. Twenty-seven were operated upon. On the whole, with this plan of expectant treatment there were 40 per cent of recoveries. Operation when indicated is feasible only if not more than 12 hours have elapsed since the infliction of the wound, if the general condition of the patient is good, and if asepsis and quiet can be secured. Schmieden is in favor of immediate operation in these cases on the battlefield—otherwise, not; rapidity and simple technique are necessary.

Projectile Fractures of Arm and Leg; Wounds and Infections of Joints.—Bier presided and Payr and Goldhammer opened the discussion. Payr said that shrapnel wounds became infected in 70 to 80 per cent and shell wounds in 90 to 95 per cent of the cases. If the injured skin and tissues are excised within the first 12 hours good results may be expected. In the treatment of fractures of the femur the best results are obtained with traction on the semiflexed limb kept in suspension or with traction clamps applied. Hemarthrosis is very common in wounds of the joints. Traction is contraindicated in these cases. Operative procedures are indicated if there are disordered function, threatened ankylosis, great pain, and symptoms of tissue incarceration. More unfavorable in their outcome than empyema of the joint are the phlegmons of the joint capsule which by their rupture often cause widespread para-articular suppurations. Goldhammer is opposed to the use of plaster of paris as the first dressing for these cases on the field. Only in the hospital is the risk of traction appartus applicable.

Surgery of the Blood Vessels, Aneurysms.—Hildebrand presided and Bier opened the symposium. He said that there came to operation 102 cases of aneurysm that had existed for from eight days to five months. The operative mortality was nearly 8 per cent. Arterial suture was performed 74 times, and suture of the wall 38 times. Both procedures are not difficult, the suture of the wall being the simpler. Operation on the sac is to be rejected. Only infection and the smallness of the artery contraindicate suture. Momburg's method of artificially emptying the vessel operated upon simplifies the operative technique.

Progress of Medical Science.

Boston Medical and Surgical Journal.

June 24, 1915.

1. Water Drinking. When Shall We Drink Water? May We Take It with Meals? E. G. Cutler.
2. The Starvation Method Versus Gradual Carbohydrate Reduction as a Time Saver in the Treatment of Diabetes. H. A. Christian.
3. Psychopathic Hospitals and Prophylaxis. F. E. Williams.
4. Program and Directions for the Mental Examination of Asocial, Psychopathic, and Doubtful Subjects. R. S. Hardwick.

1. Water Drinking.—E. G. Cutler cites the experiments of Fowler and Hawk, who found that the daily drinking of three liters of water *with meals*, for a period of five days, by a man twenty-two years of age, who was in a condition of nitrogen equilibrium through the ingestion of a uniform diet, produced the following findings: (1) An increase in

body weight, aggregating two pounds in five days. (2) An increased secretion of urinary nitrogen; the excess nitrogen being mainly in the form of urea, ammonia, and creatine. (3) A decreased excretion of creatinine and the coincident appearance of creatine in the urine. The decreased creatinine output is believed to indicate that the copious water drinking has stimulated protein catabolism. Hawk found that copious water drinking facilitates the digestion and absorption of fat for the following reasons: There is an increased secretion of gastric juice and independently of pancreatic juice as a result of the stimulating action of water. The increased acidity of the chyme brings about a more active secretion of pancreatic juice and bile. There is an increased peristalsis, due to the larger volume of material in the intestine and an increased blood pressure due to the rapidly absorbed water. There is a more complete hydrolysis of the fats by lipase, due to the increased dilution of the medium and the consequent more rapid absorption. The ingestion of large amounts of water with meals not only does not inhibit the normal flow of digestive juices, but acts as an excitant to their flow. The digestive juices are not rendered less efficient by dilution, but on the contrary, enzyme action is more complete, within limits, the greater the dilution. Even if the food were washed into the intestine more rapidly than usual, contrary to Cohnheim's belief, the greater efficiency and greater amount of the digestive juices would outbalance this. The author concludes as the result of clinical observation, supported by laboratory research, that it is advisable for people in ordinary health to drink water as desired with meals, or to the extent of from two to four or more tumblers at each repast, and that we may expect a continuance of good health in so doing, or an improvement even, provided that the food taken be first thoroughly masticated and insalivated and then swallowed and that the water be then ingested.

2. **The Starvation Treatment of Diabetes.** — H. A. Christian finds that the starvation method of Allen for rendering a diabetic sugar-free, in addition to being a safe method, has shortened very materially the time required to get a patient with diabetes sugar-free, and so permits of a large part of the patient's stay in the hospital being devoted to building up the patient's tolerance for carbohydrates. To put it another way, the method saves for the patient and for the hospital one or two weeks of time.

3. **Psychopathic Hospitals.**—F. E. Williams believes that a psychopathic hospital in addition to its other functions should serve as a prophylactic and educational station to which may come for advice and counsel those suffering from psychoneuroses and the early stages of mental disease as easily and freely, and with as little prejudice as those suffering from the early stages of tuberculosis seek out a hospital for tuberculosis; a center to which can be brought for diagnosis the supposedly backward child, before further social damage has been done; a center to which parents aware of the neurotic inheritance of their children can come for advice in their children's upbringing and protection. From its lecture platform adults should receive instruction which would lead them to a better understanding of their own complex emotions, sensations, and impulsions, and practising physicians should be instructed in the significance of certain early manifestations of mental disease, that they may be as capable in diagnosing and protecting these patients as they are those manifesting the early signs and symptoms of tuberculosis or cancer. Prophylaxis is but one of the many functions of a psychopathic hospital, but its possibilities in this direction should not be overlooked.

2. Prognostic Significance of Tuberculous Cavities. —M. Fishberg states that in very acute forms of tuberculosis cavitation is exceedingly rare and the prognosis is gloomy. In adults such cases are rare, but in infants rapid cavity formation is seen at times and the termination is almost invariably fatal. In subacute forms of phthisis, in which cavities are apt to form very rapidly, the prognosis is unfavorable unless the cavity is small. In the latter case the disease may be attenuated and subsequently pursue a chronic course with the sequestration of the affected area. Excavation is the first step toward a diminution of the acuteness of the tuberculous process in the lung. The general symptoms may be ameliorated as after the evacuation of an abscess. In chronic phthisis, cavities even when extensive are compatible with a long and efficient life. These are surrounded by a more or less dense fibrous capsule which limits their extension and are drained through a fistulous tract communicating with a bronchus. As long as the secretions are eliminated by expectoration, the patients may feel quite comfortable for years. Because they expectorate large numbers of tubercle bacilli they are often sources of infection to a greater extent than many patients without excavations. Pulmonary cavities may heal. When small, they may be obliterated by granulations or by calcification of their contents. Larger cavities may shrink, or even when remaining of large dimensions, they may become altogether benign after the necrotic tissue has been expelled. They are, however, a constant source of danger with respect to metastatic autoinfection. On the whole, cavities are an indication of chronicity of the tuberculous process in the lung, showing that the resisting forces are active and as such are less dangerous than many cases considered incipient and curable.

10. The Parathyroids and Tetany. — E. L. Hanes, summing up an analysis of the literature on the parathyroids and tetany, states that the relationship between the two is most intimate; and that in large numbers of instances the tetanies of childhood and of the puerperium, those of certain nutritional diseases, and those following operative removal of the parathyroid glands are due to the loss of or interference with the functions of these organs. It is not yet clear in what manner the parathyroids are implicated in the so-called epidemic and endemic tetanies of Frankl-Hochwart, or why certain occupations predispose to this reaction in contrast to other allied forms of labor.

2. Nature and Treatment of Bronchial Asthma.—R. H. Babcock states that if asthma is to be explained on the hypothesis of protein sensitization, then one must assume the existence of a focus in the body from which the foreign protein is absorbed or that at some period, perhaps in childhood, protein sensitization occurred, or that sensitiveness to a special protein was inherited. It may be asked why one person shows this by asthma while another does not, but instead may develop urticaria. One cannot account for this without assuming a neurosis or possibly an inherited sensitization. On the other hand, experiments with autogenous vaccines seem to indicate that the anerobic bacillus found in a case cited by the author and in all his other cases up to date is really the cause. Various foci may be the source whence protein is absorbed. Nasal polypi are not uncommon in nasal asthmatics and have been considered responsible, and the author cites a case in which the focus seemed to be a foreign bacterial poison in the gall-bladder. The first step in the treatment is the discovery and removal of the primary focus when this exists in the patient. While the vaccines are being prepared or the study of the case is not yet complete, one may use some of the old, tried remedies. Ten minims of a 1:1000 solution of suprarenal extract are in many cases highly efficacious against the paroxysm, but no line of management gives as much promise as the administration of autogenous vaccines in addition to the discovery and removal of the source of the protein infection.

3. The Treatment of Poliomyelitis.—R. W. Lovett states that infantile paralysis has been heretofore regarded as a haphazard affection of muscles, most frequent in the leg, and in the cord lesion it appears to have a purely accidental distribution, most marked in the lumbar enlargement. Possibly, however, there are other factors than the cord lesion which determine the ultimate condition of the affected muscles. An analysis made as to the frequency and severity of the paralysis shows that in cases months after the attack there are apparently existing conditions not easily to be explained by the cord lesion alone, but suggesting that function, and especially the function of maintaining the upright position, may have something to do with determining the ultimate distribution. The affection is an acute one, and treated in the early stage by rest, because paralysis is generally present in the limbs, making activity impossible, and because the patients are generally sensitive and movement and handling are painful. It seems rational not to attempt to stimulate by massage, electricity, or handling the peripheral connections of seriously disordered nerve centers, and the best accepted usage is to let such cases alone, only striving to prevent contractions until sensitiveness has disappeared, and to allow the process of repair to go on undisturbed. It is the custom to prescribe hexamethylenamine in the early stage; in the Vermont series, however, there was an interesting and suggestive case, in which a child had been taking 5 grains of hexamethylenamine for three or four days before coming down with a typical attack of infantile paralysis. With the disappearance of tenderness the time for active treatment has begun, though in severe cases it may be well to wait at least four weeks. Electricity has been overused and its value overestimated, but muscle training has a sound basis as possibly stimulating the brain centers to act on the muscles. Apparatus is needed and is not liable to promote muscle atrophy, as disuse is dangerous. If fixed deformity exists it must be corrected before active treatment can be satisfactory.

6. A Case of War Wound Infection by an Anthracoid Bacillus, the Wound Being Caused by a Shattered Trigger-guard. A. W. Sheen. With Pathological Report by B. G. Klein.

1. Cervical Gland Tuberculosis.—A. Stanley Griffith states that his investigation of cervical gland tuberculosis was undertaken as a result of the isolation of atypical strains of human and bovine tubercle bacilli from cases of lupus which had developed in the skin of the neck after excision or ulceration of tuberculous cervical glands. The object of the investigation was to ascertain whether or not tubercle bacilli raised from tuberculous cervical glands ever diverged from the standard in the same way as the lupus tubercle bacilli. In glandular tuberculosis there is marked tendency to spontaneous cure. In the author's series of the sets of glands showing definite tuberculous lesions, 29 per cent. gave negative results in culture and in animal experiment. This tendency to spontaneous arrest of glandular tuberculosis should be remembered when estimating the therapeutic effect of specific remedies. In each case the macroscopical appearances of the glands on section have been recorded with the object eventually of determining whether or not these presented differences corresponding to the type of infection. Careful comparison has not revealed any macroscopical character which is peculiar to one type of infection. On the other hand, microscopical examination would appear sometimes to yield evidence indicating the type of infection. When there are numerous short well-stained tubercle bacilli the probability is that a bovine infection is being dealt with. The proportion of bovine infections in cervical gland tuberculosis in England, while less than that in Scotland, is higher than it is in other countries. Of the four countries for which there are separate data Germany gives the lowest percentages of bovine infections. There is not much difference between the English and American percentage figures (respectively 55.5 and 51.7) for persons under 15 years of age, but for persons over 15 years of age the proportion of cases in which the infection was "bovine" is considerably lower in America than in England.

5. Complete Heart-Block.—E. Lea reports a case of complete heart-block of organic nature which showed: a persistent high idioventricular rate of 60; a period of sinal slowing to 51, during which time the auricular rate exceeded the ventricular; an unusual auricular tachycardia following atropine, to 200 per minute; and synchronous auricular and ventricular contractions during an apparent 3-1 block, such synchronism being maintained even when some degree of ventricular arrhythmia was present. Digitalis seemed to have no effect upon the rhythm or rate. Consideration of the hitherto reported cases of high idioventricular rate, relatively few in number, shows that the great pre-

ponderance of such instances is due to digitalis, whether or not the auricles are acting normally. Even when the rate is unaffected digitalis may influence the type of ventricular complex.

5. Arteriovenous Aneurysm of Femoral Artery Successfully Treated by Operation. G. G. Gillon.

1. Fatigue Dyspepsia.—G. Rankin points out that the essential etiological factor in fatigue dyspepsia is a depraved innervation of the gastrointestinal tract. The disorder therefore occurs either in persons born with a "shoddy" nervous system, or in those who have called upon a normal nervous system for efforts greater than it has been able to undertake. The end is the same in both instances—a breakdown, more or less complete, of nerve stability—with the incidence falling in the first instance and for the most part on the digestive apparatus. Every case of fatigue dyspepsia is accompanied by the same underlying phenomena of neurasthenia—loss of weight, dream-disturbed and broken sleep, capricious appetite, a constant sense of physical fatigue, failing powers of mental concentration, loss of memory, irritability, introspective uncertainty, depression of spirits, restlessness, and a firmly established conviction that the world is "out of joint."

3. Destruction of Lice.—J. P. Kinloch notes that the paraffin bodies are actively insecticidal, and of these gasolene is the most effective. Lice and their eggs are destroyed by immersion in gasolene for one minute, and may be killed by exposure to its vapor for half an hour. Powerful fatty solvents other than the paraffins are actively insecticidal. Benzene, toluene, and acetone are as toxic to lice as gasolene. Certain chlorine derivatives of methane, ethane, and ethylene are more lethal to lice than any other substances, and have the important merit of being non-inflammable. Immersion in the chlorine derivatives of ethane and ethylene immediately destroys all lice and nits, and exposure to the vapor of these substances for five minutes is equally destructive. Even soap solutions containing 2 per cent. of trichlorethylene or 10 per cent. of tetrachlorethane are capable of killing in half an hour at ordinary temperatures all lice and nits. A 25 per cent. solution of dichlorethylene or trichlorethylene in vaseline when applied to the human body has been found capable of exerting its insecticidal action for hours. The action of a 25 per cent. solution of gasolene in vaseline is of shorter duration, but is also effective for some hours. The common phenol disinfectants in their usual degrees of dilution for disinfectant purposes and at ordinary temperature fail to kill lice or nits, even after steeping for half an hour, but become efficient as insecticides if the temperature of the steeping tank is maintained at 65° C.

Berliner klinische Wochenschrift.

May 17, 1915.

Vagotonia.—Lublinski first refers to the long-known antagonism between the vagus and sympathetic nerves. Organs supplied by both must be normally in a condition of physiological equilibrium. Should vagus innervation predominate we have vagotony; should sympathetic innervation predominate, we have sympathicotony. The former is believed to be the more common. The author, adopting the conceptions of Eppinger and Hess, has studied vagotony in association with laryngospasm, asthma, and complaints of the heart and respiration. The individuals who presented this syndrome were mostly relatively youthful, often of lymphatic appearance, with slight enlargement of the lymphnodes of the neck and throat, enlarged tonsils, and at times enlarged pharyngeal tonsils, and thymus. The thyroid was somewhat enlarged in many of the female patients. There is something in the very look of vagotonia patients which suggests this condition, such as rapid change of color in the cheeks, which assume a red or blue-red tint for a brief interval; sudden outbreaks of perspiration; moist, bluish, cool hands. There are further a peculiar narrowing of the palpebral fissure, small pupils, lusterless eye, and drooping angles of the mouth. The subject swallows frequently and owing to his increased secretion of saliva must frequently wipe his lips. Not all of these symptoms are necessarily present in one subject. Further investigation shows the presence on the trunk of a very fugacious mascular eruption. A pronounced type of dermographism can be induced. As a further result of the vagus stimulation is to be noted slowing of the heart's action, often with brief intermittence. The patient feels very weak and has pain in the cardiac area. Pressure on the Adam's apple may give rise to slowing of the heart's action. To produce this (Aschner's) phenomenon the patient must have taken deep breaths, and the pressure on the larynx must be uniform. In favorable cases the pulse rate will be lowered to fifty per minute, and occasionally the heart may intermit for several seconds. When the pressure is removed and the pulse increases in frequency, there is an outbreak of sweating. The heart, however, remains slow for a variable time, and only by degrees does it regain its normal frequency. Another type of slowing of the pulse is seen when the patient lies down. When he rises the pulse bounds suddenly upward in frequency and then slowly regains its equilibrium. A third form is seen when patient squats or bends forward. The pulse in these positions may sink slowly to sixty or seventy beats. When the patient straightens up his normal rate reappears. The same slowing also occurs when the subject repeatedly flexes his knees while holding his breath. Arrhythmia from extrasystole is prone to disturb a vagotonic subject, who at the same time feels giddy and faint. This may occur while the patient is recumbent, after the slowing of the pulse. The auscultatory evidences in extrasystole show considerable variation. In order to determine whether the phenomenon is due to vagotonia or a lesion of the myocardium the atropin test is of value, as it tends to benefit the vagotonic form. Peculiarities of the respiratory rhythm also occur, expressed as laryngospasm and bronchial asthma. The bronchial asthma of young subjects is also an indication of vagotonia. The picture of the latter may be set up in some sensitive individuals by giving them pilocarpin. Entirely opposite is the condition of sympathecotonia as produced in some individuals by adrenalin. The Adam's apple stands out, the pupils are dilated, the skin and mucosæ are dry, the pulse is rapid and of high tension, the urine is abundant, and there may be glycosuria. There should be in the body a hormone, the activity of which resembles pilocarpin, the overaction of which results in vagotonia, but as yet it has not been discovered. We have, however, in atropin a natural corrective of vagotonia. The use of arsenic is also recommended as a nerve tonic.

Münchener medizinische Wochenschrift.

May 18, 1915.

Heart Disease and Warfare.—This number of the *Wochenschrift* with its military supplement contains

no less than six articles on this subject. Romberg's experience has been limited to soldiers in hospitals and private patients. Many of the latter were suffering at the time from various affections and consulted the author because of a burdensome palpitation, nocturnal oppression, or dyspnea following exertion. In such cases the heart's action was excited and accelerated, pulse small and soft, and there were functional murmurs. In not one such case was any organic lesion found. These patients were placed at rest and given sedatives and hypnotics. They responded to this treatment so well that they soon became able to rejoin their commands. This kind of cardiac mischief was to be ascribed to various febrile conditions which had originally led to invalidism, and was also associated with convalescence from any affection. In the remainder of the cases the soldiers had simply become worn out. These hearts closely simulated those which are the seat of organic mischief, and as dilatation and angina pectoris, but all signs and symptoms vanished when dilated stomachs had been remedied and omental fat removed. In but two cases was there alcoholic abuse, but overindulgence in tobacco played a notable rôle in certain patients. Neurasthenic subjects often suffered from nervous cardiac disorders as a result of war experience. Schott of Nauheim, who is now consulting physician for heart diseases in a Reserve Hospital, mentions the double implication of the circulatory and nervous systems as a consequence of warfare. Few cases of endocarditis develop in the campaigns, hence recent valvular lesions are very seldom encountered. Affections of the myocardium which were common could be attributed both to physical overexertion and psychical excitement. Hypertrophy of the left ventricle was for the most part attended by a systolic apex murmur, at times heard over the entire heart. Rapidly growing youths with narrow thorax showed under the *x*-rays the so-called drop heart and narrow aorta—this, whether they were wounded or intact, and this type of young soldier was of course very numerous. Older men, with well developed chests, however, presented the same clinical picture. The causes of the hypertrophy were to be seen in the mixture of overwork and privation, as a result of which the circulatory system becomes labile, as shown by numerous experimental tests. In excited states of the heart Schott believes in digitalis and strophanthus as well as sedatives and hypnotics. Ehret of the Marine Hospital service, who sees both soldiers and marines, finds in each arm of the service about the same percentage of cardiac affections (6 to 7). These comprise nervous palpitation, myasthenia cordis, organic affections of the myocardium, and valvular lesions. The first-named may be purely psychogenic or toxigenic (thyroidism). In direct contrast with Romberg, he finds thyreotoxic heart to be very common among the troops. Even the mildest type of this affection disqualifies for garrison duty and the graver types render the subject incapable of any military duty. Myasthenia cordis occurs in young, poorly developed subjects. Both skeleton and general musculature are subdeveloped. Physical excitement causes palpitation, and at times extrasystole. The condition appears to be psychogenic and a neurotic component may be present. The physical signs are for the most part normal. But the condition is essentially one of the heart muscle. The strain upon these weak hearts causes a condition comparable to athletic heart in the normal subject. In peace times these poorly developed youths instinctively favor themselves and the heart behavior is normal, but the soldier's life reveals the weakness of the organ. Most of these men can be patched up and placed on garrison duty. By actual disease of the myocardium the author refers chiefly to hypertrophy, and to the damage which results from acute infectious diseases, including anginas and influenza. During convalescence it is noted that these hearts are very sensitive to the action of alcohol and tobacco. Palpitation and dyspnea develop on very slight exertion. A frequent, small soft pulse is present and a permanent pulse of 120 is not uncommon. Actual chronic myocarditis is rare and due to rheumatism, syphilis, or alcohol. Aschenheim confines himself to disturbances of cardiac activity and finds that a certain constitution (unconnected with neurasthenia) is a very marked predisposing factor. The subjects are slender, delicate, somewhat excitable, lordotic, with wing-like scapulæ. Stiller's rib, deficient pileous development, small testicles, enlarged thyroid, and vague symptoms of hyperthyroidism. There is further an overdevelopment of lymphoid structures. Not all patients can be classed as having hyperthyroidism, else the genesis of the cardiac disorders would be very simple. In perhaps half of them there is only the habitus asthenicus, lymphatism, etc. The author thinks it possible, however, that disturbances of internal secretion may be at the bottom of the poor development. Drasch calls attention to the presence of cutaneous hyperesthesia in cardiac neuroses and its relation to Head's zones. Merkel in a general article states that war disorders of the heart can be treated successfully without digitalis or strophanthus, although the latter are almost universally employed.

Suppurative Arthritis in Cerebrospinal Meningitis.—Netter and Durand report the observation of this complication in 11 out of 200 cases of cerebrospinal meningitis. In most instances the larger joints were affected. In five of the cases the pus aspirated from the joints was sterile. The intraspinal injection of the antimeningococcus serum produced a speedy absorption of the pus. Suppurative arthritis of the small joints of the fingers and toes has been observed in the course of subacute meningitis with purpura in young infants.—*Presse Médicale.*

Directions for Cancer Patients.—The following are published by the New York Skin and Cancer Hospital: (1) Cancer is a serious disease which should receive constant medical care from the time it is first suspected. (2) "Cancer specialists" who advertise should be avoided. (3) Cancer is not contagious, and there is no danger of communicating the disease to others. (4) Cancer is not a disgraceful disease, and there is no reason for being ashamed of it or hiding it. (5) As soon as cancer is suspected, whether there be a lump, or sore, or other symptoms, it should be at once cared for by a competent medical man, as the earlier it is treated the more prospect there is of its being cured. (6) Anything suspected to be cancer should not be handled or squeezed, but should be kept from all irritation, as all this spreads the trouble and renders the cure more difficult. (7) When it is decided that a surgical operation is necessary this should be done completely at the earliest possible moment; delay is dangerous. (8) The proper medical treatment of cancer should never be neglected, both at the very beginning and also after an operation has been performed. (9) It is not necessary to operate on every cancer, *x*-ray and radium are often of value, and the disease may disappear and remain absent under proper dietetic and medical treatment. (10) This treatment consists in an absolutely vegetarian diet, with continuous proper medication, for a long time. (11) To get favorable results this treatment should be kept up strictly until discontinued by the physician.

Insurance Medicine.

THE GENERAL FACTORS DETERMINING MEDICAL SELECTION.

FROM "ALLGEMEINE LEBENSVERSICHERUNGSMEDIZIN," BY PROF. DR. GEORG FLORSCHÜTZ OF GOTHA.

(*Continued from Vol.* 87, p. 1082.)

Certainly beer does possess these fattening qualities, for according to the proverb "where there is a brewery there is no need for a bakery," and the absolute amount of nutritious constituents taken up with large consumption of beer, is in fact very considerable. If we proceed with the supposition that a beer drinker takes ordinarily 2 liters of beer daily, we find that this amount contains about 90 grams of carbohydrate and 14 grams protein, *i.e.*, the drinker obtains from beer of the first named one-sixth, and of the latter one-eighth of the total daily adult requirement of these substances. To this it must be added that most of the alcohol contained in the beer is oxidized, as a result of which certain constituents of the body, notably the fats, are protected from consumption, or in other words, spared. Hence the nutrient value of beer is actually to be estimated as high. Norton, however, deprives the fat man who is a beer drinker of every prospect of a long life, for to his corpulence must be added the toxic action of the alcohol, which subjects we shall later discuss more in detail.

If it is the superfluous nutriment which is responsible for the corpulence, one can judge it less harshly; but we must not forget that it is not free from danger. Why does corpulence become dangerous? Quite generally expressed, it is because it entails greater demands on the vascular system. In 57 dissections of corpulent subjects Chambers found the heart normal in but 7. Thirteen had died of dropsy, 11 of apoplexy, and 15 of chronic nephritis.

Moses, who tabulated the death material of the Victoria Life Insurance Company during the period 1899-1905, found the chief causes of death in the corpulent to be diseases of the heart and kidneys and apoplexy.

An interesting study of obesity and its significance for life insurance has been published by the Assicurarconi Generali of Trieste. It has, indeed, like the investigations of Moses, only relative value, for it is based only on the deaths and does not consider living risks. Nevertheless, aside from this, it is carried out so completely that the results merit full attention as serviceable hints. The total number of deaths was 6840, grouped according to the constitution on admission and to the later causes of death, and the following table shows in percentages which part the several constitutions—spare, medium and fat—played in the causes of death:

Causes of Death	Spare	Medium	Stout
Tuberculosis	25.7	13.1	4.1
Apoplexy	4.9	9.2	12.3
Diseases of circulatory apparatus	9.4	14.8	22.7
Pneumonia	11.7	10.3	7.7
Malignant neoplasms	6.4	8.3	7.1
Infectious diseases	5.4	4.6	4.1
Diseases of the central nervous system	10.6	9.8	6.6
Suicide	4.7	5.1	4.1
Miscellaneous	21.1	24.8	30.5

We will only refer in passing to the cumulation of tuberculosis cases in the spare, for what interests us here particularly is the rotable supermortality from diseases of the circulatory organs in the corpulent. A more intimate study of the figures shows that 18.25 per cent. of the corpulent individuals died of heart disease alone, and 8.61 per cent. of chronic nephritis—figures which confirm the statements of Moses that the principal causes of death in the corpulent are diseases of the heart and kidneys and apoplexy.

For this reason a very careful investigation of the vascular system is the most important requirement in the medical examination of the corpulent, and the chief factor in the prognosis. First, we have to deal always with the insurability of the corpulent in general, and then, when all factors seem to be favorable, with the enrollment of the individual in the group of insured which corresponds to the hazard. For the really corpulent subject is always a substandard risk. The Gotha Life Insurance Bank has found in the case of corpulent subjects that, despite the selection, the supermortality amounted to 26 per cent.

It now becomes more intelligible why life insurance places so great a value upon measurements and how difficult, though, has it been to persevere with the demand for exact body measurements—how difficult it still is at times. For the great value of body measurements is even to-day not everywhere recognized. We may leave it undecided whether the blame should rest upon the circumstance that the medical examiner does not otherwise make use of the tape, or whether in his constant bacterial-orthodox thinking, he does not lay sufficient weight upon the conception of the constitution. It is a fact that body measurements give occasion in every-day insurance practice to the most frequent delays and crossquestionings. And how little is accomplished of fundamental value in this manner? Yes, but this little may place the general status of the applicant on a mathematical basis, may place the subjective judgment of the examining physician by a quite objective conception, and thereby supply to the medical director the data required for the judgment of the individual case.

(*To be continued.*)

Questions in Insurance Application — Expert Evidence as to Existence of Disease Held Conclusive.—A question in the medical examination of an applicant for a benefit certificate asked if any member of the applicant's household was affected with consumption, or had been affected within the last two years. A negative answer was given. In an action on the certificate it was held that the question was not limited to living members of the applicant's family, but included as well members who had died within the two-year period, and hence the negative answer was falsified by proof of the death of a son of the applicant from tuberculosis within two years prior to the application. Two physicians testified that the insured died from pulmonary tuberculosis, and one of them testified that, as early as April 15, 1911, before the insured applied for the insurance in question, she was suffering from that disease, and that he made a culture which developed tuberculosis germs. It was held that the testimony of ordinary laymen that, during the time prior and subsequent to the date of the certificate, the insured was apparently well, was about the house doing her household work, etc., was insufficient to raise an issue on the question. In a disease of this character, the testimony of laymen could not be considered against testimony by reputable physicians.—O'Brien v. Brotherhood of American Yeomen, Michigan Supreme Court, 150 N. W. 130.

MECHANOTHERAPEUTICS IN GENERAL PRACTICE. By G. DE SIVIETCHOWSKI, M.D., M.R.C.S., Fellow of the Royal Society of Medicine; General Assistant, Electrical and Massage Department, King's College Hospital, London. Price, $1.50 net. New York: Paul B. Hoeber, 1914.

THE writer calls attention to the harvest reaped by the quack in the domain of mechanotherapy, because of the passive attitude of the profession, and remarks upon the consequent loss to the patients in a number of affections. This book should prove useful as a practical guide to massage in general practice, as there are a number of illustrations and clear descriptions of the various movements.

DIE ENTSTEHUNG UND BEHANDLUNG DER KARZINOME. Von Hofrat Dr. A. THEILHABER in München. Berlin: S. Karger, 1914.

HOFRAT THEILHABER enumerates as probable causes of cancer old age, climacterium, scars, blunt trauma, chronic inflammation of long duration, certain callings, alcoholism, the transmutation of benign tumors, cachetic states, psychic depression, parasitic irritations, syphilis, tuberculosis, and the hypofunction of the hematopoietic organs. He believes it extremely probable that the degeneration of the connective tissue cells and faulty blood supply are important causative factors. As prophylaxis, he recommends Bier's hyperemia, diathermy, and the treatment of old scars and of breasts after mastitis by suction. Two annual blood lettings of from 300 to 400 c.c. according to the weight of the body, are also suggested by the author. His treatment consists, of course, of extirpation of the tumor in operable cases. In hopeless cases there should be continual diathermic treatment and roentgenization, injection of extracts of thymus, spleen and uterus, and in some instances the roentgenization of the generative glands.

DER SALVARSANTOD, seine Ursache und seine Verhütung. Intravenöse oder intramuskuläre Salvarsaninjektion? Von Dr. CARL SCHINDLER, Spezialarzt für Hautkrankheiten in Berlin. Price, 4.80 Marks. Berlin: S. Karger, 1914.

THE author is an advocate of the intramuscular injections of undiluted salvarsan prepared analogously to "joha" which he tested with his former chief, Geheimrat A. Neisser. When the patient is carefully selected, the author believes intramuscular salvarsan injections to be harmless and efficacious when 40 per cent. salvarsan oil is used. Only from one to two of such injections are necessary for a cure. Invalids with grave organic, functional, or degenerative alterations should not be treated at all with such a highly concentrated arsenical preparation in Dr. Schindler's opinion.

A BIOGRAPHIC MEMORIAL OF GEORGE MCNAUGHTON, M.D. Edition limited to 200 numbered copies. Price, $2.00 net. Brooklyn, New York: Albert T. Huntington, 1914.

A BEAUTIFUL and fitting tribute indeed is here presented in memory of one who has already won a monument in the hearts of his colleagues, friends, and patients. As stated in the preface, "this brief composite biography is intended to fulfill a triple purpose—to serve as a slight recognition of the man and his public service; to uphold the objects and interests for which he strove; and to act as a memento for his friends, a convenient reference and something tangible to preserve." William Browning contributes a brief sketch of the life of George McNaughton, who was born at Mumford, Monroe County, N. Y., on July 4, 1856, and who died on March 17, 1914. He gained distinction in his chosen branch, gynecology, but he had already attained considerable success in the practice of intubation, of which he was the pioneer in Brooklyn. Dr. McNaughton was identified with every movement that made for civic betterment and the advancement of the profession. The McNaughton genealogy is discussed by J. M. Winfield, who also describes his work at the County Medical Society. Reminiscences are contributed by C. F. Barber; a Personal Appreciation is presented by A. M. Judd; an article on his Use of Sea Water in Internal Therapy is written by F. L. Crawford; his Work in Intubation and Abscess of the Throat is described by W. C. Braislin, and his Treatment of Sterility is discussed by D. S. MacNaughton. R. L. Dickinson contributes Remarks on the Death of George McNaughton, and a closing tribute is written by William Schroeder, Sr. The bibliography of McNaughton is appended. The volume is illustrated with eight full page plates showing birthplace, residence, instruments devised, etc. The cover is embellished with the plaid of the McNaughton clan. The entire volume is one that may serve as a type of memorial volumes of medical men who have gained and have earned distinction.

STUDENTS' MANUAL OF GYNECOLOGY. By JOHN OSBORN POLAK, M.Sc., M.D., F.A.C.S., Professor of Obstetrics and Gynecology, Long Island College Hospital; Professor of Obstetrics in the Dartmouth Medical School; Gynecologist to the Jewish Hospital; Consulting Gynecologist to the Bushwick, Coney Island Deaconess' and Williamsburg Hospitals, Brooklyn, and the Peoples Hospital, New York; Fellow American Gynecological Society, etc. Illustrated with 100 engravings and 9 colored plates. Price, $3.00. Philadelphia and New York: Lea & Febiger, 1915.

THE chief virtue of this book is its conciseness. Theoretical discussions are omitted, and the important facts in the pathology, symptomatology, and diagnosis of the diseases of women are presented in a form available for easy study and quick reference. The various gynecological operations are described and illustrated with clear drawings. The chapter on gynecological diagnosis is a particularly helpful one. Throughout the book one notes the rare element of originality combined with rich clinical experience and didactic skill. This is perceived in the admirable chapter on malignant tumors of the uterus in which are clearly and definitely presented the earlier and later symptoms of these tumors. An excellent colored plate accompanies this chapter. One is favorably impressed with the full and detailed directions for treatment which are given in this volume.

A TEXT-BOOK OF THE PRACTICE OF MEDICINE for Students and Practitioners. By HOBART AMORY HARE, B.Sc., M.D., Professor of Therapeutics, Materia Medica and Diagnosis in the Jefferson Medical College of Philadelphia; Physician to the Jefferson Medical College Hospital. Third Edition, Revised and Enlarged. Price, $6.00 net. Philadelphia and New York; Lea & Febiger, 1915.

ONE of the principal characteristics of Hare's Practice has been its practicality and this has been maintained in the new edition which has recently appeared. The progress in fields of medical endeavor has naturally made necessary numerous changes in this revision so that many of the sections have been practically rewritten. The work is thorough, complete, and attractively written, and should prove a very satisfactory text-book. The press work is of high grade and the text quite free from typographical error. One important one occurs on page 162, in which the dose in the Schick test reads 1/15 of a minimal lethal dose. It should of course be 1/50 of the m.l.d. for a 250 gm. guinea pig.

PRACTICAL SANITARY SCIENCE: A Handbook for the Public Health Laboratory. By DAVID SOMERVILLE, B.A., M.D., M.R.C.P., Lond.; D.P.H., Camb.; F.C.S. Assistant Professor of Hygiene and Public Health, with charge of the Laboratories of Hygienic Chemistry and Physics, University of London King's College; Examiner in Bacteriology and Chemistry, B.Sc., University of Glasgow; Examiner in D.P.H., University of Aberdeen; Medical Officer of Health, Harrow; Late Demonstrator of Physiology in the Medical School of St. Thomas's Hospital. Second edition. Price, $3.50 net. New York: William Wood & Co., 1915.

THIS little book gives a summary of the course of practical lecture demonstrations given to the Department of Public Health at King's College, London. It outlines the more important and reliable procedures, chemical, physical, and bacteriological, for the examination of water, soils, sewage, foods, alcoholic beverages, and disinfectants. Preference is given to methods which are practical and have proved generally reliable. This fact, together with the compactness of the volume, make it a most valuable handbook for the practical worker in a public health laboratory or as a textbook for the student of sanitation.

The second edition differs from the former one in the arrangement of the chapters, the addition of considerable new material, and in changes in the appendix, in which are outlined some of the less frequently used analytical operations.

Society Reports.

ASSOCIATION OF AMERICAN PHYSICIANS.

Thirtieth Annual Meeting, Held in Washington, D. C., May 11, 12, and 13, 1915.

(Special Report to the MEDICAL RECORD.)

(*Concluded from Vol. 87, p. 1007.*)

Thursday, May 13—Third Day.

Aleucemic Lymphadenosis.—Dr. T. B. FUTCHER of Baltimore reported this case and discussed the blood picture as well as the clinical course of the disease and the differential diagnosis.

The Occurrence of Sprue in the United States.—Dr. EDWARD J. WOOD of Wilmington, N. C., made a preliminary report in which he referred to practically all the published records of this disease occurring in the United States except those contracted in the tropics. He laid emphasis on the fact that the classical form of the disease was found in Porto Rico. It was shown that clinically there was a close resemblance between sprue and the so-called "pellagra sine pellagra." In both diseases there were stomatitis, painless diarrhea, decrease in the size of the liver, emaciation, and an unfavorable course. In pellagra it was shown that finally the nervous system would suffer while in sprue this was not usually the case. It was shown that there were some differences in the stools and tongue in the two diseases. Sprue might be confused with amebic dysentery. The lack of a definite chemical reaction in sprue feces was to be deplored. There was a growing belief in the relationship of sprue with some form of pancreatic insufficiency. The important point, however, was the confusion now existing in the South between sprue and pellagra. It was unwise to diagnose pellagra without the skin lesions or a definite history of such lesions.

Summary of Studies in Cortical Decomplication, with Remarks on the Nature of Certain Irritative Lesions.—Dr. E. E. SOUTHARD of Boston presented a paper which concerned itself especially with histological examinations of the cerebral and cerebellar cortices and pointed out that modern neuropathology was no longer so much interested in lesions of an extirpatory nature, but had become concerned with lesions in which complex tissues like the cerebral and cerebellar cortices became simplified in disease. The effect of tissue simplification were not necessarily paralytic since in many instances the decomplication left the fundamental mechanism intact and destroyed merely phylogenetically recent shunt mechanism. Important differences between the cerebral and cerebellar cortices in this connection were presented.

An Unusual Condition of the Blood in Primary Pernicious Anemia.—Dr. NATHAN E. BRILL of New York presented this paper. He said that splenectomy as a therapeutic measure was not founded on adequate knowledge of the conditions underlying the pathogenesis of Addisonian anemia. It was at best but a tentative measure, which might and probably would be discarded when the ultimate results of its influence became more fully known. It was utilized in the treatment of the following patient with disastrous results: A woman, 43 years old, mother of five children, patient non-syphilitic, presented all of the classical signs of a primary pernicious anemia, which began one year ago, insidiously, with gradually increasing sense of fatigue and later weakness with disturbed gastric symptoms, *e. g.*, vomiting for three weeks, eructations of gas. Six weeks before coming under observation weakness became extreme and the skin pale and light yellow; visual power markedly diminished; cardiac palpitation, tinnitus aurium and vertigo complained of; there had been no bleeding from the mucous membranes or into the skin. Six pounds were lost in weight during the year. Physical examination on admission to the hospital revealed a yellow skin, a slightly enlarged liver, a relatively larger spleen which could be felt over three ccm. below the costal border; tender tibiae and sternum and a blood picture of high color-index (1.5) and the associated conditions of the cells indicating the presence of an anemia gravis. A transfusion of blood was done, followed in thirty-six hours by a splenectomy; following this an absence of the usual bone-marrow reaction was noted, though there was a gradual physical improvement in the patient, to the extent that she could walk again without the distress which had previously existed. In five (5) weeks after her discharge from the hospital there was a furibund recurrence in her symptoms which brought her back to the hospital in a worse condition than at any previous time. The blood then showed a tremendous loss of red blood cells, an increased activation of the leuko-blastic and the erythro-blastic tissues of the bone-marrow, the circulating blood containing early myelocytic forms of cells, "myeloblasts or myelogones," of which a large number were phagocytic, containing one or more red cells in their cytoplasm, a myelocytosis of 21 per cent., all accompanied by a hemoglobinemia and hemoglobinuria with the final blood picture of an acute myeloid leukanemia (v. Leube) immediately before death. No autopsy could be obtained. The query was "What relationship, if any, had the splenectomy on this unusual activation of the bone-marrow?"

Spontaneous (Nontuberculous) Pneumothorax, Illustrated with Lantern Slides.—Dr. ELLSWORTH SMITH of St. Louis presented this communication and said that pneumothorax occurring in the course of other diseases, notably pulmonary tuberculosis, was not such an unusual event, but when developing suddenly in an individual apparently perfectly healthy it was quite a rare affection. Lantern slides were shown of the various diseases in which pneumothorax might develop, and its comparative frequency as a complication in these diseases. The writer also showed the entire number of cases of spontaneous pneumothorax reported from 1826 to date, and gave a brief analysis of these cases from the standpoints of sex, age, side affected and duration. He discussed the cause, symptoms, physical signs, recurrence, treatment and results. He said there were two main theories as to the cause: (1) Rupture of a latent tuberculous focus; (2) rupture of an emphasematous bleb.

A Study of Nephritis.—Dr. PHILIP KING BROWN of San Francisco, Cal., presented a paper which dealt with the incident of nephritis with high blood pressure among 7,000 cases entering the Southern Pacific Hospital for various reasons, in which the finding of albumin in the urine called attention to the kidney condition. He spoke of the occurrence of infections in all such cases and the influence of occupation and infection, especially syphilis.

The Occurrence of a Chronic Streptococcic Bacteriemia before and during the Development of Signs of Endocarditis.—Dr. JOHN A. OILLE, Dr. DUNCAN GRAHAM, and Dr. H. K. DETWEILER, introduced by Dr. A. McPHEDRON of Toronto, Canada, presented this communication. A non-hemolytic streptococcus had been recovered from fifteen cases of endocarditis during the last four or five months from patients in the Toronto General Hospital and in private practice by a method similar to Rosenow's. These results were obtained fairly readily by investigation such as time permitted of only a small proportion of the number of cases in which a bacteriemia was suspected. Most of these cases were very early and the signs much less marked than those of streptococcus viridans endocarditis described by Osler, Schottmüller, Libman and others. The cultures were obtained in one case before any sign of endocarditis was present and in three or four where signs were questionable, consisting of soft systolic murmur in the pulmonary area. In four cases in which opportunity has been had for watching the development of mitral regurgitation, the murmur was just heard in the second interspace to the left of the sternum. There was other evidence that a systolic murmur in the pulmonary areas was most often a transmitted mitral murmur most often heard over the left auricular appendage. A rise of temperature so slight that it would ordinarily escape observation unless it were taken systematically for a period of two or three weeks as for the early diagnosis of tuberculosis, *i.e.* reaching 99° or 99.5° at irregular times of the day, without evident cause, suggested endocarditis in most cases. However, three or four had a normal temperature when the cultures were obtained. In seven or eight cases the diagnosis was obscure and was cleared up by taking a blood culture. Tuberculosis, "neurasthenia," and chlorotic types were closely simulated. Nervous symptoms such as irritability, restlessness, hypersensitiveness, attacks of crying, mental depression, and "nervous breakdowns" were characteristic. Family incidence was a prominent feature. A recurrent tonsillitis was the commonest precursor of the disease. Only three of the cases had ever had acute rheumatic fever.

The Medical Cure of Gastric and Duodenal Ulcer by an Efficient Removal of Gastric Juice Corrosion.—Dr. Bertram W. Sippy of Chicago presented this communication. Favored by unusual clinical facilities, the writer said he had gradually evolved and established in practice a method of treating gastric and duodenal ulcers. The method was based on old and well-established facts of physiology and well-recognized principles underlying the healing of ulcer. Results of treatment were far beyond early expectations. After an experience of twelve years the writer was convinced that the vast majority of cases of gastric, and more particularly duodenal ulcer now treated surgically, could be readily and more quickly cured by the management advocated. The principle involved in the treatment advocated consists essentially in protecting the ulcer from gastric juice corrosion. This was accomplished by maintaining an accurate neutralization of all free hydrochloric acid, thus rendering the digestive action of the gastric juice inert during the entire time that food and its accompanying secretion were present in the stomach. Excessive night secretion, when present, was also controlled. The neutralization of hydrochloric acid was accomplished by frequent feedings, and the use of alkalies in carefully regulated, but adequate, quantities. Experience in all types of individuals under widely varying conditions had abundantly demonstrated that the corrosive action of the gastric juice could be thus practically annulled until healing of the ulcer was accomplished.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held April 15, 1915.

The President, Dr. Walter B. James, in the Chair.

This program was arranged by the Section on Obstetrics and Gynecology.

The Logical Interpretations of Menstrual Irregularities.—Dr. John G. Clark of Philadelphia read this paper, in which he stated that in the majority of uterine hemorrhages the source of the trouble usually lay in young individuals in the ovary, and in adults in the uterus. Both before and after menstruation there was a slight increase and then a decrease in the general metabolic activity, as shown in the respiratory rhythm, rise and fall in the bodily temperature, acceleration and then slowing of the pulse rate, and a greater followed by a smaller nitrogenous output. After the cessation of the flow there was a rapid return to normal and then a state of physiological equilibrium which obtained for about fourteen days. After this preparation for menstruation began again. Coincident changes in the glands of the endometrium occurred; immediately after menstruation the quiescent gland was slender and more or less straight; later the lining epithelium underwent active karyokinesis, gradually assuming the form of a columnar mucous cell, which elaborated more and more mucus until the maximum was reached just before the flow began. The activity of the ovary governed the menstrual flow. In making a diagnosis between benign and malignant growths the application of this cyclic law was of the greatest assistance. One might safely say that the initial symptoms of a myoma or a polypus never manifested themselves as an accidental spotting of the patient's linen unless a preceding period of increasing flow at the regular menstrual epoch had occurred, whereas exactly the reverse was true in carcinoma. A malignant growth was never governed or materially influenced in the production of symptoms by the cyclic law. All bleeding that did not occur synchronously with the physiological menses was to be viewed with grave suspicion until it had been proven to be benign; on the other hand, a regular periodicity of flow with intervals of complete freedom from even slight bleeding might be regarded with equanimity so far as the diagnosis of cancer was concerned. The author stated that, in making a diagnosis in a case of suspicious hemorrhage, if during a period of quiescence a slight degree of traumatism produced a flow of bright red blood malignant change was indicated, but if the bleeding was due to a myoma, a polyp, or an endometritis, this would rarely be the case. In order to apply the test the cervix was exposed with a bivalve or trivalve speculum, and its surface carefully cleansed with 1-1000 solution of mercury bichloride. The speculum was then slightly tilted and filled with the solution until the external os was submerged. A uterine sound was then gently passed, under direct vision (never by touch), through the clear pool in the speculum into the cavity of the uterus. The sound was gently rotated in all directions. After a complete circuit had been made it was gently withdrawn, and the external os closely observed for a short time. If a *thin* stream of bright red blood trickled into the pool of clear fluid this might be regarded as highly suspicious of malignancy. Such a case should at once be subjected to curettage and a microscopic examination made to ascertain the exact pathological condition. If the flow of blood did not occur the evidence was strongly against malignancy. This sign was to be regarded only as a contributory means of arriving at a diagnosis and was only to be employed with the technique described.

Dr. William L. Clark of Philadelphia said he had devised and practiced the desiccation method for the reduction of adventitious growths of the skin and accessible mucous membrane, and since its field of usefulness in anatomical locations of interest to the gynecologist had been proven by clinical experience, a presentation of facts concerning it might be of interest. His experience with desiccation in gynecology had been limited to neoplasms and some other lesions of the urethra labia, vagina, perineum, bladder, uterine cervix, anus, and rectum. Curatively desiccation was indicated for the following abnormalities: venereal warts, leucokeratoses, condylomata, moles, pigmentations, chancroids, angiomata, chondroma, pruritus of nervous and eczematous origin, lupus, fissures of the vagina and rectum, polypi, papillomata of the bladder, vagina, cervix, and rectum, erosions of the cervix, hemorrhoids, localized epitheliomata, and rodent ulcer. In applying heat he sought the point at which the effect was somewhat more than hyperemia and less than carbonization and this he called the desiccation point. This word was chosen because it described the effect upon the tissues, which was that of dehydration. Just enough heat was used to devitalize tissues without carbonizing them. The disadvantage of the desiccation method was the expensive and complicated apparatus. In the treatment of malignant disease the speaker had adopted a classification which he had formulated for personal guidance. First for cutaneous surfaces desiccation had been in his hands almost uniformly successful in localized epitheliomas and rodent ulcers of the skin. The destruction was carried beyond the diseased areas for some distance to insure thorough eradication. The blood and lymph channels were sealed on account of which there was less likelihood of metastasis. When a large area was involved a course of *x*-ray treatment following the desiccation was advisable. Desiccation would heal lesion that the *x*-ray alone would not heal. Localized lesions with metastases were usually unsatisfactory no matter by what method they were treated, and no claims were made for desiccation except in conjunction with radical operative measures, when the field might be desiccated after operation in suitable cases to seal blood vessels and lymph channels and to reach points that perhaps the scalpel did not reach. In some cases radium might be used with advantage in conjunction with desiccation and the Roentgen rays, but unless a sufficient quantity was available it had better not be used, as the speaker had seen many cases stimulated to rapid growth by using an insufficient quantity of radium. In localized cancer of the mucous membrane the results of desiccation compared favorably with those obtained in localized skin cancer. In absolutely inoperable cases of cancer, desiccation as a palliative measure had advantages over the curette and cautery, for the reason that a general anesthetic was unnecessary, there was less inflammatory reaction, and accessible diseased tissue was destroyed, sterilized, deodorized, and bleeding was stopped. The cervix when cancerous was peculiarly insensitive to desiccation and could usually be treated as radically as desired without even a local anesthetic. In postoperative recurrences desiccation had a field of usefulness. In accessible sarcoma if seen early desiccation was a good treatment. In advanced sarcoma the same general rule applied as in carcinoma.

Dr. John O. Polak of Brooklyn said that it seemed to him that only with a basic knowledge of the physiological and histological processes involved in uterine hemorrhages was it possible to properly interpret the clinical history and approach the subject of uterine bleeding with any rational understanding. Dr. Polak called attention to the fact that many of these hemorrhages were produced by varicosities of the broad ligament. These hemorrhages were of definite type, profuse and always attended with premenstrual and menstrual pain in each inguinal region, and there could

be found an explanation why the woman who had had, for instance, twin pregnancies or multiple pregnancies, or was of the ptosic type, was subject to excessive menstruation because of varicosities of the broad ligaments. In the hemorrhages that occurred when a woman approached the menopause, there was encountered a hyperplastic change in the tissues which surrounded the blood vessels; the blood vessels could not retract and go through the normal hemostatic process. If one kept in mind the congestion and involution attendant upon every menstrual period of the endometrial layer, one could understand how changes in the blood vessels, in the wall of the uterus, and in the endometrium were bound to produce pathological conditions. He thanked Dr. Clark for the suggestion that cancer was a corrosive process; this term made the difference between pathological, physiological, and malignant changes clear.

Dr. Lawrence W. Strong said he thought something should be said regarding the structural changes, something that would be more characteristic of the uterus itself in the so-called idiopathic hemorrhages. He was glad to hear Dr. Clark lay so much stress on the ovary, and to have him state that the structural changes were mostly conspicuous by their absence. The vessel changes were not characteristic in these hemorrhages. Dr. Schwarz who had been working with him in his laboratory had shown that in menorrhagic uteri such changes were not at all characteristic. Changes in the endometrium which had been regarded as characteristic had also been shown not to have any real causative relationship. Regarding idiopathic hemorrhages no structural changes had been demonstrated.

Dr. Robert Tilden Frank said Dr. Clark had given them a masterly presentation of his subject and that he had nothing to add or subtract on the clinical side of the subject. But when it came to an explanation of the cause of hemorrhages occurring in fibroids, idiopathic hemorrhages in the young, as well as those occurring at the climacteric, he agreed that the ovary was the trigger and the uterus the gun. But the smokeless powder had not been mentioned. He thought their attention ought to be turned to the chemical side of this subject. He had with him a few slides that would illustrate the fact that the uterus, both musculature and mucosa, with all their components, responded to chemical stimuli. Therefore the anatomical and morphological study of minutiae was love's labor lost. Slides of a menstruating mucosa and from a menorrhagia case which were thrown on the screen showed that neither was distinguishable from the other. Slides were shown of the uterus of rabbits. In each case the rabbits had been castrated, except for controls, and had been injected with potent placental and corpus luteum extracts. Depending upon the number of injections and the extracts used, varying degrees of hypertrophy had resulted in the muscle and mucosa. The time had arrived to direct their attention to the motive cause of the uterine changes. Whether fibroid or idiopathic hemorrhages, castration produced amenorrhea and involution. As soon as they understood the ovarian changes, the uterine would become clear, and minor variations in vessels, muscle, or mucosa would be of subsidiary importance.

The Technique of Applying Heat in the Treatment of Inoperable Uterine Carcinoma. — Dr. J. F. Percy of Galesburg, Ill., presented this paper in which he stated that the method which he would describe for the treatment of inoperable uterine cancer depended for its effectiveness upon the fact that carcinoma was destroyed when the mass was raised to a temperature of 113° F. or 45° C., while normal tissue cells were not affected until the temperature reached from 132 to 140° F., or 55 to 60° C. The purpose of the treatment was to secure a coagulation, and not a carbonization of the tissues involved. This "cold iron" method permitted not only a greater penetration of heat in the cancerous mass, but the rectum, bladder, and ureters were in much less danger of being injured by a degree of heat sufficient only to make the pathological tissues thoroughly hot. A practical method of determining the amount of heat necessary to inhibit further growth of a cancer mass was to grasp the mass in the hand, encased in a No. 11 rubber glove. The surgeon could tolerate a temperature of 115 to 120° F. without receiving a burn of the first degree. It took from ten to twenty minutes after the iron had been in the mass for an appreciable change in the temperature to take place even in small growths. If too great heat were used and a charcoal core formed, it was necessary to remove it with a curette. The curette should never be used before the heating iron even for the purpose of getting a specimen for diagnostic purposes. The heat sealed lymphatics and blood vessels, preventing the further dissemination of cancer and mixed infection. In applying the technique the patient was prepared as for a simultaneous abdominal and vaginal section, making a free incision and packing off the abdomen from the pelvis. The ovaries and tubes were removed and both internal iliac arteries were tied. If this was difficult then both the uterine arteries should be ligated. With the use of this low degree of heat hemorrhages were frequent and hence it was of advantage to tie off the blood supply. While the operator was exploring the abdomen to determine the extent of pelvic involvement, an assistant could dilate the vagina to the size desired for the introduction of the water-cooled speculum. The entire vaginal surface was painted with tincture of iodine or Harrington's solution. With the water-cooled speculum in place the heating iron could be applied to the malignant mass. If there was no evidence of cancer except at the uteri-cervical junction, it was wise nevertheless to pass the heating head to the fundus of the uterus. If the proximal end of the cervix had not been softened by the pathology it would be found difficult to reach the fundus unless a cautery knife was used. The best way of doing this was to use a cautery heat sufficient to cut through the cervical canal laterally and vertically. The heating head must not be removed from any involved structure until the part was so hot that it could not be held in the gloved hand. When carcinoma cells had invaded the vaginal walls the most practical method was to use the water-cooled speculum open at the top and the angular thermometer placed in the urethra. With this speculum and the heating iron lying on its bottom and raising the temperature in the urethra to 120° F., a sufficient degree of heat was obtained to kill carcinoma if it was maintained for ten minutes, and it would not destroy the sphincters or injure the caliber of the urethra. The author also described the technique where the base of the bladder was involved and where the rectal mucous membrane had been fixed by the cancer. For the production of heat the author preferred the electric current to the gas stove and cartridge shaped heating heads. The final after-treatment of these cases should be with the deep penetration method of the *x*-ray. Patients should report every six weeks for the first year. The patient before beginning treatment should be made to understand that the procedure might have to be employed several times. About 50 per cent. of the cases thus far treated required a reapplication of the heat. Practically all the patients thus far subjected to this form of treatment belonged to the utterly hopeless type so far as their treatment was concerned; the author felt convinced that a surprisingly large percentage of them could be transferred to the hopeful class by a technique not as formidable as a well-executed Wertheim operation.

Dr. Howard C. Taylor said he could not see the indication for the use of heat in cancer of the fundus uteri. In advanced cases with ascites and general abdominal metastasis the case would be obviously inoperable and the abdomen should not be opened. In another class of cases, at first believed to be operable, but in which, after the abdomen had been opened, metastases might be found in the liver, intestines, or elsewhere, although the uterus was freely movable, the removal of the uterus in order to relieve local bleeding and discharge would be safer and more effectual than the use of heat. In still another class of cases of carcinoma of the fundus uteri, if the case was found to be inoperable on account of direct extension of the growth from the uterus to the ovaries, intestines, etc., the removal of the uterus and also the use of heat would be contraindicated on account of the great risk and small benefit. The use of heat was therefore limited practically to cancer of the cervix. All appreciated the value of heat in some inoperable cases of cancer of the cervix uteri. These cases were sometimes so greatly benefited that the uterus became movable and the case became operable. Would Dr. Percy perform an operation in such cases or would he rely on the application of the heat?

Dr. Hermann J. Boldt said that after Dr. Percy had demonstrated his technique to him about a year ago he had come to the conclusion that the main feature in this method of treatment was the opening of the abdomen, thus enabling one to do more accurate and efficient work. In his opinion this was the only way in which such good results could be obtained. So far as

the difference between the application of high or low degrees of heat were concerned, from the clinical aspects he was not at all satisfied that the application of the low degree of heat was any better than the high, because, in his experience, the clinical results had been practically the same. Septic infection might be the cause of death when a low degree of heat was used. One of his cases had died only that day, eight days after cauterization. On the fourth day after the application of heat there was secondary sloughing and a vesical fistula developed which was quite large. With the application of the higher degree of heat he had had but one death caused by secondary hemorrhage. He could see no reason for believing that the application of a low degree of heat was more likely to cause bleeding than the high degree. They needed more definite details as to results.

Dr. George H. Mallett stated that he had assisted Dr. Percy at the Memorial Hospital that afternoon. With very few exceptions all of the cases of uterine cancer referred to that institution were considered inoperable and incurable. He had seen Dr. Byrne perform his galvanocautery operation in which there was difficulty in preventing injury to surrounding parts by heat radiation, and difficulty of keeping the platinum at a low temperature. Dr. Percy had overcome both of these difficulties and placed this valuable agent on a more scientific basis by his carefully worked out technique. In the cases treated this afternoon the uteri were fixed by infiltration in the cellular tissue and by masses in the parametria. With his hand on the uterus in the abdominal cavity, it was surprising to feel these masses oozing away through the application of heat in the cavity of the uterus and to observe how movable the uterus became. It was surprising that Dr. Percy did not apply this treatment to the early and operable cases for if it would kill the cancer cells at a distance of two or three inches from the heating iron, it would destroy all cancerous tissue in the uterus and the parametria as well, and thus avoid the necessity of a hysterectomy with its high mortality.

Dr. Le Roy Broun expressed the opinion that the technique of the application of heat for the treatment of uterine cancer as suggested by Dr. Percy was a decided improvement over other methods which they had previously used. In the former methods in which the abdomen was not opened, the cautery ends had been known to pass through the uterus and as a result patient died. For this reason the operator was careful, as a rule too conservative, and stopped short of the cauterization needed or of that which was possible. He believed that the low heat applied for a considerable length of time had a greater penetrating power than the previously used hotter dull red heat applied for a shorter time. The selection of the kind of inoperable cases in which this method should be used was of much importance. The value of the "cold iron" method consisted in its deep destructive penetration. On this value also rested the danger. Sloughing of the ureter or sloughing of the uterine artery with delayed hemorrhage might occur. Dr. Percy had related four such instances and the speaker knew of another, and also of several instances of delayed hemorrhage. With this knowledge the cases suitable for the Percy method of cauterization should be carefully selected in order to avoid as far as possible the likelihood of such complications. Personally, the speaker preferred to limit the choice of cases to those in which there was induration of the basis of one or both broad ligaments. When the involvement extended beyond the cervix there was a strong possibility of the effects of the effort to do thorough work involving the uterine artery and resulting in late arterial hemorrhage. Dr. Broun said he confessed that he dreaded the possibility of this late hemorrhage. The suggestion of tying off the anterior trunk of the internal iliacs as a preliminary step to the cauterization, Dr. Broun said he did not regard with favor since there were too many subsidiary vessels involved in ligating this vessel. The suggestion of tying off the uterine artery as a preliminary step he had never done, but this might be an addition. The only objection was the necessary dissection in order to separate it from the underlying ureter and the possibility of suppuration in the separated areas as a result of the subsequent deep cauterization. The Percy method seemed to him especially adapted to the nodular or ingrowing type of cervical cancer as opposed to the papillary or cauliflower type. At the Woman's Hospital they felt very grateful to Dr. Percy for having personally supervised the making of a set of his instruments for the hospital. His technique was now used throughout the hospital to the exclusion of the older red heat methods. For that class of cases in which the uterine disease extended beyond the cervix and in which he hesitated to use deep cauterization he still had some hope in the desiccating electrical treatment as carried out by Dr. William L. Clark of Philadelphia and in the effect of the deep penetration of the rays of the Coolidge tube.

Dr. Percy again emphasized what he had said in the first paragraph of his paper, viz., that it was extremely difficult to describe his technique. The extensive application of the heat that he made was difficult to appreciate from the mere verbal description. In reference to his statistics about which Dr. Taylor had inquired, Dr. Percy said he realized that this was the *crux* of the whole situation. He was not ready to publish his statistics for the reason that he was dealing with a class of patients with a condition in which the mortality was 100 per cent. All that he could say was that in this mass of hopelessness in which he had applied his technique, there were a respectable number that were alive months and years afterwards with no signs of recurrence of any sort. With increased experience in the application of his technique it became more effective and less difficult, and the results were becoming more encouraging. In the last two years an increasing number of surgeons were interesting themselves in his technique and the reports from their clinics were substantiating any claims he had made. The results in his earlier work were mostly palliative. He did not stop hemorrhage and pain and offensive discharge, but he had used a cauterizing temperature and thus failed to get the maximum penetration of heat which was the essential thing. Cancer of the fundus which had been referred to by Dr. Taylor was a rather rare condition, but he had had cases in which the utero-cervical junction alone was apparently involved. He had applied the heat and had had these cases return in one or two years with a recurrence in the body of the uterus. This was the type of case that would apparently justify a Wertheim or panhysterectomy in four or five months following his technique. Dr. Percy said he had reports of twelve cases from leading clinics in this country in which all the tissues thus removed had been worked up in serial sections and no evidence of carcinoma found. He was sure they would all agree that these twelve extensive operations were unnecessary ones. His personal objection to a Wertheim or a panhysterectomy was based on his experience with the recurrences that came to him after these operations had been performed. There was not enough tissue left in which to develop heat without too extensive destruction. If a Wertheim or a panhysterectomy were done, it should only be done after some months following the application of the heat by his technique. Dr. Percy said he was glad Dr. Boldt had emphasized the importance of opening the abdomen as an essential and valuable part of this procedure. But he could not agree with him that it made no difference whether one used a high or a low degree of heat. His experimental work absolutely settled the question in favor of the low degree of heat. The high degree of heat formed a charcoal core about ⅛ inch thick and ¾ inch in diameter, which was stiff as a piece of sewer pipe. This left the greater part of the gross mass of cancer in the pelvis uninfluenced by the heat, and in addition, prevented drainage, which was dangerous to the patient because of the excessive absorption of broken down cancer cells. This technique was the only one that did destroy the gross mass of cancer at one sitting. It left the patient to be treated for the small points of metastases that might be left by any of the many recognized methods of treatment, operative, *x*-ray, radium, or serums. More than all else, it permitted in the speaker's opinion, the acquired resistance which had slowly but insufficiently developed during the destructive process of the disease to assert itself. This could and did in many cases clear up the remote but small points of metastases not reached by the primary application of heat.

Paratyphus-A Infection in Infancy.—Lagane reports a case of this condition contracted by an eight-months'-old infant from its mother. The course of the disease was similar to that of typhoid fever. There were pronounced torpor and somnolence. There was moderate diarrhea and the spleen was not enlarged.—*Bulletin de la Société de Pédiatrie de Paris.*

MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, Held March 15, 1915.

THE PRESIDENT, DR. THOMAS S. SOUTHWORTH, IN THE CHAIR.

The Relation of Arteriosclerosis to Ophthalmology, Neurology, and Surgery, from the Viewpoint of the Internist.—Dr. LOUIS F. BISHOP, in this paper, said that arteriosclerosis, the disease, was a process which, when neglected, uniformly resulted in hardening of the tissues; the arteries frequently being the tissues most conspicuously involved. The sclerosis was the lesion resulting from the disease, and not the disease itself. The manifestations of this met with in the fields of ophthalmology, neurology and surgery represented the various stages of a degeneration of arteries which the art of internal medicine had failed to control. The disease which led to these lesions consisted of a disturbance of metabolism, leading to a damage of the individual cells by particular proteins with which the cells were unable to deal with successfully, and such disturbance consisted of a sensitiveness of the cells resulting from some cause analogous to parenteral ingestion of a protein, and usually occurred at the time of some severe illness, acute poisoning, or great nervous strain. The essential treatment consisted of the discovery and removal of the offending protein, and the general management of the disease was hygienic, involving a strict diet depending on the food relations of the individual, well-regulated exercise, and appropriate medication. The programme for the evening pertained to the discussion of the end-results of a process which, having started, proceeded for perhaps five years without symptoms and a few years more with only obscure manifestations, and frequently was recognized only when the sudden occurrence of retinal, nasal, uterine or prostatic hemorrhage, of hemiplegia, or of gangrene imperatively attracted attention. The time to treat arteriosclerosis was at the beginning, but much more could be done for even terminal cases than was generally supposed. Free phlebotomy, strict diet, enforced exercise, the avoidance of improper drugs, and the use of proper drugs had often checked the process when no one could have ventured to promise such a consummation. In the course of the paper Dr. Bishop stated that there was an original observation which he had long had in mind, but had never formally submitted to the judgment of a medical society, and this concerned the gross appearance of the eye in arteriosclerosis. He remembered that several of the eminent clinicians who were his teachers had spokn of the "shininess of the eye" in what was then called chronic Bright's disease, and the supposition was that it was caused by an edema of the eye, although it was present in many cases in which no evidence whatever of edema elsewhere was observable. The conviction had grown on him that this change in the appearance of the eye in arteriosclerosis was a visible manifestation of the cellular irritation which he believed to be the cause of arteriosclerosis, and in the earlier stages of the disease he had in many instances noted that so long as the patient followed a strict regimen the appearance referred to was no longer to be seen, but just as soon as there was a recrudescence of the disease, it returned. The sensitization of the conjunctive to protein irritation of external origin under certain circumstances was well recognized, and was made use of by serologists; and he could see no reason why the cells of the conjunctive should not be sensitive to unfriendly proteins circulating in the blood.

Arteriosclerosis as Seen by the Ophthalmoscope.—Dr. WILBUR B. MARPLE, having stated that nowhere else in the body but in the retina was it possible to see the blood-vessels and study their peculiarities and changes, remarked that if the oculist were careful and appreciated the opportunity presented by persons consulting him on account of presbyopia, for investigating the patient's vascular apparatus, he would often discover the danger-signals pointing to beginning arteriosclerosis, and be in a position where he could be of the greatest possible service. He then described, with the aid of sketches taken from life, certain characteristic features of the normal fundus, mentioning that it was at the points of grossing of a vein by an artery that the first retinal abnormalities suggestive of arteriosclerosis were discovered. He next took up in turn the changes, in arteriosclerosis, in the calibre of the arteries, the "silver wire" appearance of the arterial twigs, the pathology of the changes, and the markedly irregular distribution of vascular disease in the retinal vessels; after which he cited, with extensive comments, several illustrative cases. Later on he remarked that while he thoroughly appreciated the importance of the sphygmomanometer, he was not at all sure that it was wise for the ophthalmologist to use it promiscuously, especially on account of the moral effect on the patient, who nowadays was apt to be so extremely apprehensive. He was convinced that it was far better, for the patient, to leave all sphygmomanometric investigations to his family physician or the internist to whom he should be referred. It might not be difficult for a novice to put on a sphygmomanometer and read off the blood-pressure, and the exhibition might impress some patients; but we all knew that it took all the skill of an expert internist to accurately measure and appreciate the exact significance of the systolic, diastolic and pulse pressures. Indeed, the ablest workers in this field were not at all agreed even among themselves in regard to many problems in blood-pressure. Personally, therefore (and he thought this should be the rule among ophthalmologists), he invariably referred these patients to their family physicians, or to an expert internist, to whom the matter of investigating the blood-pressure legitimately belonged.

The Field of Surgery in Arteriosclerosis.—Dr. JOSEPH B. BISSELL said the relation of surgery to arteriosclerosis was intimate and important. Recognizing this trouble as a disease of the tissues, and not merely a hardening of the arteries as such, the surgeon found himself of necessity concerned with all those processes which have a degenerative influence upon the tissues and which can be in any way controlled or altered by surgery. The arteriosclerotic variety of degeneration was met with extremely often, and it was a type differing from others in having as its characteristic a definite infiltrative or exudative change, rather than the simple chemical one of degeneration. Chronic appendicitis and chronic gall-stone conditions were almost invariably followed by arteriosclerosis. Vaughan had pointed out that bacteria cause harm, not because they are live organisms, but because they act as foreign proteins, and that when the system becomes sensitive to their particular protein they cause irritation to the cells, leading to destruction and sclerosis. Billings had frequently spoken of pyorrhea alveloris as the precursor of arteriosclerosis, and the same result seemed to be true of any chronic suppurative process. Hence it was our duty to urge correction, as far as possible, of such conditions, whether found in the mouth, gall bladder, intestinal tract, or elsewhere. In the presence of chronic bacterial growth the damage done was at first slight or even negligible, but a warning of approaching trouble might be obtained by an early examination of the fundus of the eye. If it were found that the arteriosclerotic process was impending, surgical attention should not be delayed. At various periods in the course of this the diseased conditions of the vessels might be more or less localized, and when the arterial fibrosis was circumscribed the question of mechanical exclusion of the involved area at once arose in the surgical mind. The indication for arteriovenous anastomosis was narrowing, occlusion or obstruction of the artery, with consequent ischemia of the part supplied by the distorted circulation. Carrel's feats in suturing blood-vessels in animals had been remarkably successful, but, unfortunately, as much could not be said of the same class of operations in humans. In many instances the immediate result had been satisfactory, but the outcome disappointing; no case of complete and lasting recovery having as yet been recorded. Halstead and Vaughan had reached the conclusion that there was but one indication for the application of arteriovenous anastomosis, *i.e.* in traumatic destruction of a principal artery where end-to-end union of the vessel was impossible. In patients suffering from arteriosclerosis, besides the possibility of arterial rupture when reducing a difficult dislocation or in performing that reprehensible procedure, the breaking up of an old contracted joint, the surgeon should recognize the danger, from a resulting thrombosis or embolism, in tight bandaging, as well as the likelihood of serious damage following the use of the Bier method of local hyperemia. Uusually these patients tolerated anesthesia fairly well, provided they had no marked cardiac or renal complication. The struggling caused during a badly administered anesthetic, or surgery performed under inadequate anesthe-

sia, was more dangerous than the anesthetic itself. In these cases secondary hemorrhage was an ever threatening danger, and the possibility of gangrene of amputation wound flaps, or of gangrene of the wound margins and of the failure of union in otherwise clean operations, was always present. Intestinal wounds were peculiarly unfavorably influenced by arteriosclerosis, and hemorrhages in various parts of the body from friable vascular structures were a usual symptom calling surgical attention to the disease. Among its earliest effects were various nutritional changes leading to the necessity for operative interference, and an important matter was the relation of blood-pressure to operation. It was requisite that whenever possible patients with very high pressure who were to be operated upon should be prepared by a period of preliminary treatment. In these cases surgical procedures called for great caution, and during operation the surgeon should be ever ready to heed the warning of a sharp fall in the blood-pressure. One of the most available measures in the treatment of patients suffering from high blood-pressure was judicious venesection. Even though high blood-pressure were only a symptom, and phlebotomy only a temporary expedient, in the speaker's experience this procedure was usually the cause of great and permanent relief. Venesection, when properly advised and adequately performed, undoubtedly prolonged life and gave the opportunity for other and perhaps more permanent measures to be employed in the successful treatment of this very prevalent and often fatal symptom complex known as arteriosclerosis.

Epistaxis in Arteriosclerosis.—Dr. CHARLES E. PERKINS said that although in the spontaneous nasal hemorrhages requiring treatment the bleeding might possibly come from any part of the nasal mucous membrane, a large majority of these were arterial and came from the anterior portion of the septum. Normally the vessels supplying this region were supported by the mucous membrane and covered with ciliated epithelium, but there was no part of the nasal mucous membrane so liable to erosion as this. Erosions here were as a rule not serious affairs and readily healed, either with treatment or in consequence of a change in atmospheric conditions, but with increased blood-pressure the vessels in this area, having lost their support, perhaps also part of their wall, gave way. When hemorrhage took place from one of the small arteries of the part it was sometimes startling to see how free it was. Some of these patients bore the loss of blood poorly; they were more liable to faint than other persons. In treating such cases, if we were called while bleeding was taking place, our first duty was to stop the hemorrhage. This was done by passing a cotton pledget soaked with adrenalin well into the anterior nares and, if necessary, making pressure against the septum with the finger upon the ala. Reapplication of the pledget might or might not be required, and as soon as it remained dry on removal the point from which the blood had flowed was cauterized, preferably with a bead of fused silver nitrate. If the artery were seen running up to this point, the silver bead might be applied at one or more points along its course, in order to obliterate it. The patient was then to be supplied with adrenalin and instructed how to apply the pledget and make suitable pressure. In case, as occasionally happened, the bleeding point were further back, we passed our pledgets much deeper into the nares, endeavoring to exert pressure upon and bring the adrenalin in contact with the area from which the hemorrhage came. If in this way the bleeding could not be promptly arrested, and the blood-pressure were very high, remedies should be given to reduce the latter as quickly as possible. As a last resort it might be necessary to plug the posterior nares. Although this procedure was a very easy one to carry out, and was fairly certain to arrest the hemorrhage, it was not free from danger, as the blood, under pressure was liable to flow into the middle ear, maxillary antrum, or frontal sinus, and might be the cause of suppuration in any of these cavities. As to the desirability of arresting the hemorrhage in all cases, Dr. Perkins said he had always felt it his duty to stop the bleeding as soon as he could and to prevent its recurrence. He was prepared to believe that in florid types the bleeding had done no harm, but he thought that such persons had lost all the blood required for therapeutic purposes before he saw them. In the anemic cases there could be no doubt that loss of blood was undesirable in every way.

Arteriosclerosis with Relation to the Control of Uterine Hemorrhage.—Dr. WILLIAM P. HEALY said that as to the influence of arteriosclerosis upon uterine hemorrhage, he thought we must distinguish two groups of cases; first those in which arteriosclerosis was associated with changes in the heart, liver or kidneys leading to a condition of passive congestion of the pelvic organs from obstruction to the circulation, and thus inducing uterine hemorrhage indirectly; second, those in which the sclerosis was particularly marked in the uterine vessels, without special evidence elsewhere of its presence. The arteries of the uterus were subject to the same influences tending to produce sclerosis of their walls as the other arteries of the body. Moreover, there could be no doubt that menstruation, abortion, pregnancy and inflammation of the uterus were important factors leading to the development of sclerotic changes in the uterine vessels. These cases all occurred in women who had reached or passed the menopause and in whom a persistent bleeding, either menorrhagia or metrorrhagia, took place. The hemorrhage might be severe and uncontrollable except by hysterectomy, and this operation was frequently required for its arrest and to save the patient's life. Careful clinical examination of the uterus and adnexa were negative, as also were, frequently, microscopical examination of scrapings from the uterine canal, which were not apt to show the sclerosed vessels because these did not always lie in the endometrium. On microscopical examination of the removed uterus it was found that the smaller vessels in the mucosa were increased in number, while their walls were thickened by a deposition of fibrous tissue with well-stained nuclei; and the same was true of various vessels throughout the entire substance of the uterine walls, which were thus heavier and more dense than normal, with the vessels presenting themselves prominently all over the cut surface. The clinical diagnosis of this condition was extremely uncertain, and had to be made by exclusion, after careful bimanual examination and curettage had revealed no other cause for the hemorrhage. While the common form of treatment for persistent bleeding from sclerosis of the uterine vessels had been hysterectomy, the *x*-ray was now often effective, and it might be used without fear of any harmful action on the ovaries, on account of the age of these patients. Recently Kelly and Burnam had reported very excellent results in the control of such uterine hemorrhage by means of radium. It would seem advisable, therefore, that in these cases a trial should be made of radiation, either with the *x*-ray or radium, in which the danger of serious complications was practically nil, before subjecting the patient to the risk of such a severe operation as a complete vaginal or abdominal hysterectomy, which under the best conditions was apt to have a mortality of from 2 per cent to 3 per cent.

Arteriosclerosis with Relation to Prostatic Operations.—Dr. TERRY M. TOWNSEND read this paper prepared by himself and Dr. JULIUS J. VALENTINE. It was stated that while arteriosclerosis and prostatic hypertrophy might be coincidental in the same man, clinical experience had shown that the two conditions bore no causal relation to each other. As to what conditions justify the risk entailed in surgical operative procedure, and what conditions prohibited this, in a patient with obstructive prostatic hypertrophy and arteriosclerosis, the comparatively sparse literature on the subject showed a general agreement on fundamental principles, but marked disparity in clinical experience and results. When the urologic surgeon was called upon to make the decision as to whether or not he would remove the prostate in an arteriosclerotic, it was not any one factor which outweighed another, but the large composite clinical picture of those vital systems which control life, that had to be taken into account. Specifically, the heart, kidneys, and nervous and hemic systems needed the closest study, and since the operation was one of election, there could be no excuse for the omission of careful preoperative study of these essentials. The condition relative to operative procedure of the cardiovascular system, the kidneys, the nervous system, the coagulability of the blood, precocious arteriosclerosis, and the general state of nutrition and the emunctories were then discussed, together with the operative technique and postoperative care. The conclusions reached were as follows: The clinical composite making up the picture of arteriosclerosis does not contraindicate prostaectomy. If the heart functionates moderately

well, arterial hypertension is negligible, since it is amenable to reduction by preoperative preparation or automatically declines after operation. In the presence of all cardiorenal contraindications, the two-stage prostatectomy has been, and can be frequently carried to successful termination. The utmost care must be given in the preoperative and post-operative periods, and the operative technique should be certain and rapid.

Arteriosclerosis in Its Relation to Life Insurance.—Dr. HENRY F. QUACKENBOS said that the early detection of sclerosis, as revealed by abnormally high blood-pressure, had come to be regarded as of pre-eminent importance in the examination of applicants for policies, as even more significant than the presence in the urine of a few casts or a trace of albumin, which might be only transient. In other words, life insurance examiners had begun to look not only for indications of the actual existence of cardiovascular-renal disease, but for symptoms suggesting its imminence in the future. It could not be long before inquiry would be made regarding those habits of life which accounted for the appearance of such symptoms, as the conviction existed among all investigators that hypertension is the undisputable forerunner of organic complications which will shorten the life of an apparently well man. The quality of an insurance risk had to be determined by the daily habits of an applicant, inasmuch as those habits paved the way for either a premature breakdown or a green old age. It was probably no exaggeration to ascribe 50 per cent. of all deaths of insured persons to the hypertension and sclerosis consequent upon the sedentary, unhygienic kind of life lived by a majority of our population, either directly or indirectly as the proximate cause of pneumonia, bronchitis, pulmonary edema, and allied conditions. Overeating, through the immediate action on the vascular system of irritant poisons formed in the intestines, created hypertension, and this was the unambiguous cause of arteriosclerosis which might eventuate in apoplexy or, by overtaxing the heart, induce pathological myocardial conditions or lead to renal disease. The automobile habit had stolen from our business men and well-to-do women the opportunity for exercise which a necessity for walking so freely offered, and this was thus breaking down constitutions where the remoter bicycle habit had upbuilt them. It had crept into the rural districts also, and as the dwellers there were also depriving themselves of health-giving exercise by the employment of farm machinery, they were not as good risks as formerly. The increased death-rate in this country during the past twenty years (from 27 to 38 per 10,000), which was rightly attracting the attention of life insurance companies, could not be laid to general causes, but rather to habits of living which had developed with the refinements of civilization—notably the excessive consumption of alcohol, tobacco, and proteid fare, and the lack of active exercise to oxidize the food and carry off the accumulated poisons. Dr. Rogers, chief medical director of the New York Life Insurance Company, had stated that there were numerous cases which would formerly have been regarded as normal insurable lives which were now rejected by reason of high blood-pressure, and that in his experience the underlying cause of hypertension in 50 per cent. of the cases was intestinal toxemia, and in most of the remaining 50 per cent., habitual overeating. Now as intestinal poisoning was due to erroneous diet, it was fair to assume that over and improper indulgence at table explained the abnormally high arterial tension in the majority of these applicants. In addition to the questions now appearing in the examiner's certificate, "Do you use malt or spirituous liquors in any form? Daily quantity? Do you use tobacco in any form? Daily quantity?" the speaker predicted that within a few years would be put the equally important inquiries, "What do you eat, and how much?" and, "What are your habits of exercise?" Cases of blood-pressure exceeding the probable safe limit, when kept under observation, had been found sooner or later to show albumin and casts, and likely to terminate in Bright's disease or apoplexy. It was to be remembered, however, that many cases of arteriosclerosis have a normal, or even subnormal blood-pressure. Low blood-pressure was less significant from the life insurance viewpoint, though an adult pressure under 105 was regarded as suspicious. It was interpreted as implying diminished powers of resistance, and in persons belonging to tuberculous families or living amongst unhygienic surroundings as intimating quiescent tuberculosis. The appalling strain to which human beings were subjected in our modern civilization might perhaps be evolving a stronger race, one better adapted to endure it, but a life insurance company was without prescience, and could not intelligently select from the ranks of those who were playing with fire the few who would not be burnt.

Dr. REYNOLD WEBB WILCOX said that in arteriosclerosis it was necessary to recognize the interdependence between the general condition and the local condition; the former might be slight, the latter marked. For this reason, in his book, he had designated the affection usually known as chronic interstitial nephritis as chronic arterial nephritis. In some instances the general condition, arteriosclerosis, was marked, and in others, not, and this should be kept in mind in order that the best therapeutic results might be obtained. High blood-pressure and arteriosclerosis were by no means synonymous or coextensive, and high blood-pressure was not necessarily an accompaniment of advanced life. It was quite possible to have a low blood-pressure in association with arteriosclerosis, as was shown by an investigation of 1,200 patients whose ages ranged from 66 to 98 years. Whether or not we accepted Dr. Bishop's theory of the reaction of the body cells which become sensitized against certain proteins, we would all probably follow out the dictates of our palates and appetities. Personally, he was convinced that the matter of sugar tolerance was quite as important as the sensitization of the proteins, if not more so. The sphygmomanometer must be recognized as an instrument of precision, and it bore the same relation to therapeutics as the clinical thermometer. He could not but believe that the passing of high-blood pressure as a fetish would be looked upon by the physician with considerable regret, but by the scientific internist with much satisfaction.

Dr. BEVERLEY ROBINSON said that while the case for very great consideration for high blood-pressure and hardened arteries (arteriosclerosis) had been admirably presented to-night, he felt somewhat tired of everywhere hearing about these things nowadays. Like the exaggerated call to operate in appendicitis and the furore as to the dangers of tuberculosis, was this latest obsession in the popular mind. He was one of those who greeted with enthusiasm all real advances in medical science, provided common sense and humanity governed their use and popularity; but when, in this present medical fashion, he saw the sphygmomanometer applied to the poor victim's arm in season and out of season, he felt called upon to protest. This was an instrument that must be used with skill to be of any value, and must be considered from a broad standpoint in order to obtain a proper appreciation of its findings in relation to diagnosis, prognosis, and indications for treatment. Yet too often it was applied in a haphazard way and to the same patient under such opposite conditions as to render it worse than useless. After deploring the present over-specialism in the profession, and expressing the opinion that no man should become a specialist until he had laid a secure foundation by arduous general work, the speaker referred to the matter of treatment. As to what could be done here, we could, he said, change bad habits; we could try to put a veto upon excessive eating and drinking and to get the patient to stop worrying, and we could cry a halt to overwork. We should not, however, be in too great a hurry to change radically the habits of a lifetime, though we could limit the number of drinks, cigars, and courses at meals. We could also say emphatically, "Go to bed early; take a rest. You must occasionally go on a trip and live in the open—in the woods or at the seashore, as you prefer." As to drugs, we might give them—the iodides and the nitrites—for a time, and while unpleasant or threatening symptoms prevailed; but if, after a while, blood-pressure still remained high despite all that we could do advisedly, we should then stop the drugs and regard the hardened arteries and high blood-pressure as nature's protection to the individual. Otherwise we would find a lowered heart impulse, a feeble, wavering pulse, a loss of spirits, and an introspective preoccupation which boded no good.

Dr. THEODORE K. TUTHILL said that, from clinical observation and physiological study, he was more and more inclined to accept the following five propositions as a working basis for the care and treatment of cases of arteriosclerosis: First, that arteriosclerosis

was a result of and secondary to increased blood-pressure. Second, that blood-pressure increase was due to a toxin or toxins. Third, that blood-pressure increase was a physiological process, conservative in character and necessary to conserve physiological function when toxins were present. Fourth, that blood pressure per increase *per se* called for no treatment, except rarely in the presence of a threatened crisis, and then only temporarily. Fifth, that elimination of the existing toxins, as far as possible, through the body drainage system, and correction of faulty nutrition by an adjusted dietary, constituted the best treatment. The first proposition he knew would raise the question, Why do we find arteriosclerosis associated at times with low blood-pressure? To this he would answer that when such was the case the patient had reached the secondary stage of the disease, which was characterized by low blood-pressure, and was in the greatest danger.

Dr. Richard Cole Newton, of Montclair, N. J., said he believed that all persons were more or less toxic, and that Dr. Bishop's anaphylaxis theory was correct. There was no reason why people should not keep fit, for, as Parkes had said, training was only an expression of a proper method of life. Overeating, he thought, was more responsible for general ill health than drinking wine or spirits. In the country, living conditions were more favorable than in the city. Not only was there more fresh air, but the people ate less rich food, and led a generally simpler life. Personally, he had for some years been a vegetarian, but he had now modified this practice, and felt much better off for a little meat. For most persons he thought that a certain amount of meat was desirable.

Dr. Victor A. Robertson said he had had the opportunity of seeing several cases of arteriosclerosis affecting the uterus, and in none of them was there evidence of this condition in other parts of the body. All were characterized by profuse hemorrhage, which did not yield to drug treatment, and only temporarily to curettage. In two instances it had been necessary to resort to hysterectomy and an examination of the removed organ showed marked degeneration of the muscular tissue and increase of connective tissue, in the shape of bands running through the uterine walls, while the walls of the arteries, the lumen of which was diminished, were much thickened, with the muscular coat largely replaced by connective tissue. In all the cases the uterus was found, on bimanual examination, to be moderately and symmetrically enlarged and of firmer consistency than normal, and the diagnosis had to be made by a process of exclusion.

Dr. Edward E. Cornwall said he was not in sympathy with the tendency shown by some of the speakers to belittle the importance of arteriosclerosis and of careful examination of patients for its signs and symptoms. While no doubt too much was often made of some of the latter, he thought the morbid condition in question was one which merited the gravest consideration. In speaking of this condition generally he preferred to use the term cardiovascular disease, because that of arteriosclerosis pointed to only one of the three principal pathological foci around which the clinical manifestations of the condition clustered, so to speak; the other two being chronic myocardial degeneration and chronic nephritis. Cardiovascular disease, in spite of the extent and diversity of its pathology and clinical symptoms, possessed a distinct unity, which appeared particularly in the etiology and the interrelationships of its different manifestations. Looked at broadly, the disease consisted of a wearing out, as a whole or in parts, of the great apparatus for supply to the tissues material for their metabolism and carrying away waste products. Its causation was to be found in heredity, physical and mental overstrain, and exposure to effect of poisons, namely, those of the infectious diseases, those directly introduced into the body, and those manufactured in the body itself. The general treatment of the disease was prophylactic and palliative. Those born with a cardiovascular apparatus of inferior material should early recognize the fact and live in such a manner as to subject this apparatus to less than the ordinary amount of strain and of toxemic irritation; and everyone, if he would insure himself against this disease, should take similar prophylactic measures. After the disease was established the necessity for the careful life and an "easy" diet was, of course, apparent. Probably the most effective element in the treatment was the regulation of the diet, namely, by limiting the amount of food to the actual needs of the body and by selecting articles easy of digestion, comparatively free from purins, and comparatively insusceptible to injurious fermentative and putrefactive changes in the alimentary canal.

Dr. William R. Broughton said that in his practice he observed two classes of cases. In the first the patient came for distinct symptoms of arteriosclerosis which affected the vision, such as retinal hemorrhage, and these cases were already known to the patient's physician. In the second the disease was in its incipiency, and the cases usually appeared in patients who came to have their eyes examined for glasses and who had no suspicion of any such trouble as arteriosclerosis. In these cases, where there was any suspicion of arterial change, he employed the sphygmomanometer without unnecessarily alarming the patient, and if the amount of blood-pressure appeared to confirm the diagnosis of arteriosclerosis he immediately communicated with the family physician. As almost every person over 50 had to come to the ophthalmologist to have the eyes examined for glasses, his responsibility in this matter was very great, and a routine examination of the fundus should be made.

Dr. J. J. Connellen, after referring to the unreliability of renal function tests and urea nitrogen estimation, said as regards bacterial toxins as the cause of arteriosclerosis, he was convinced that the different sugars bore an all-important relationship, and that where the different toxin-producing types of bacteria were present the best results in their elimination could be obtained by cutting out such foods as those on which they prospered. No real or scientific method of dieting could be advocated, however, until we had separated the different types of bacteria in the intestine in relationship to their growing in different sugar bases. All kidney diseases, with the exception of those due to calculus or to colon or tuberculous infection, he believed to be of toxic origin, either following an infectious disease or long-continued absorption of toxins from the intestine. He had frequently noticed in a so-called renal irritation of marked type, showing casts and albumin, with or without a few red blood-cells, that when the intestines had been thoroughly cleaned out the renal irritation ceased to exist.

Cultivation of Tissues in Vitro.—D. Thomson concludes that the tissue of various animals, including mammals and man, can be cultivated *in vitro* in a medium composed of fowl plasma one part, plus extract of chicken embryo one part. It would appear that all proliferating cells tend to elongate and throw out processes in a solid plasma medium, whereas in a fluid medium they retain their original shape and appearance. The cells of different tissues however retain certain distinguishing characteristics in the plasma medium, so that these cells evidently have some inherent points of difference from each other which remain with them regardless of the medium of environment. Complete uninjured portions of chick embryonic tissue grow to some extent *in vitro* under somatic control. The chick spleen is embryonic life at least is capable of producing red corpuscles as well as various forms of leucocytes. The extract of one species of animal tissue appears in certain cases to stimulate the growth of tissue from an animal of different species, whereas in other cases the converse seems to hold good. Extracts of certain tissues deposit stars of crystals resembling tyrosine when kept in the incubator for a period of two weeks and upwards.—*Proceedings of the Royal Society of Medicine.*

Follicular Odontoma and Three Dental Cysts.—F. St. J. Steadman reports the case of a woman aged 34, who presented when first seen five months ago, a fairly large, fluctuating, non-inflammatory swelling in the right upper premolar and molar region. There was a retained deciduous canine on this side. The permanent canine had not erupted. The skiagram showed this swelling to be apparently a follicular odontoma in connection with this unerupted tooth. No fewer than three small dental cysts were then noticed in connection with three buried stumps. A few septic teeth and stumps were removed, and the mouth allowed to heal. The odontoma was then removed in the usual way. The removal of the sac presented no difficulty. During the operation it was found that the tumor actually penetrated the bony floor of the antrum. The canine was lying behind the root of the lateral incisor. It was found necessary to remove the latter tooth in order to reach it.—*Proceedings of the Royal Society of Medicine.*

THE BACTERIAL FLORA OF TREES AND MEN.*

By STEPHEN J. MAHER, M.D.,

NEW HAVEN, CONN.

In the hope of making my subject interesting, I have taken advantage of the fact that the maker of the annual address in medicine is allowed some privileges of speculation and of order of statement that would not be desirable in strictly scientific discussion. Nevertheless, no deductions herein recorded are without bases of experimental support.

For the purpose of keeping the motif and nomenclature of this address clear and uninvolved, I wish you to consider all bacterial life as divided into spore-bearing bacilli, non-spore-bearing bacilli, cocci, and a fourth class to include yeasts, molds and the higher forms. As to this fourth class I will have very little to say to-day.

In the test tube when a spore-bearing bacillus reaches the limit of its power of vegetative growth, either because it has covered the surface of the hard medium on which it has been planted, or because it has produced a sufficient amount of toxins in liquid media to inhibit its further development, each little rod transforms itself into ovoidal or round shapes sometimes thicker than the original rods and sometimes less thick. These shapes, the spores, are the resting stage of the bacillus. They undergo no further change as they grow older except to thicken their outer capsule, and to become somewhat more resistant to such harmful influences as heat and acid. Of course as soon as they are transplanted to a favorable environment they grow again into rod shapes and multiply as rods.

In nature when the spore-bearing bacillus finds its life threatened by cold or by starvation, or by poisoning from its own secretion, it becomes a spore or two spores. When its environment is merely difficult, not threatening, the bacillus lengthens out into filaments or develops internal coccal granules.

The only spore-bearing bacilli that cause disease are the bacillus of anthrax and the bacillus of tetanus and the gas bacillus. Considerable attention has been everywhere paid to these three spore-bearing bacilli as well as to cocci and yeasts and non-spore-bearing bacilli, because they so frequently produce disease. But the harmless spore-bearing bacilli that we often drink with our milk and that we always eat with our salad, have received very scant attention indeed from medical text-books, or medical teachers, or medical research workers. The argument for neglecting them is that no disease comes from them. My argument for the need of studying them is, that all germs that cause disease come from them. That is a pretty strong statement, but I hope to be able to stagger your incredulity without bewildering you with too many technical details. And if I succeed in convincing you, or even interesting you, I will give you a new power for grappling with many of the difficult problems of medicine and hygiene.

Where Spore-Bearers Exist Alone.—For the purpose of this address it is important to learn if there are any places in nature where only spore-bearing bacilli grow. While on a mid-winter visit to a medical friend in the Adirondack Mountains some years ago, he and I debated the question, is there any bacterial life in this cold mountain air? My friend's view and the belief of all the scientific men thereabouts was that this glorious dry air, 10° to 50° below zero, was germ free. To decide the matter we made many interesting experiments during the next week with the following results:

Spore-bearing bacilli in pure cultures grew on all petri plates of agar exposed out of doors before snowfalls, during snowfalls, or after snowfalls. Spore-bearing bacilli, pure except for an occasional mould from the thicker twigs, grew from the foliage of all the evergreen trees in the mountain forest, whether near to the village or distant. Of course all the technique of getting the leaves was as careful as alcohol lamps, sterile jars, and freshly flamed instruments could make it.

I have repeatedly exposed agar plates to outdoor air in New Haven in winter and in summer. After rain storms in summer and after snow storms in winter, and sometimes during snow storms in winter, the incubated plates have yielded only columns of spore-bearing bacilli. At all other times outdoors, and at all times in-doors, the colonies of spore-bearing bacilli have been mixed with colonies of various kinds of cocci, non-spore bearing bacilli, and moulds. Plantings of blades of grass have invariably given me only pure cultures of spore-bearing bacilli, provided the blades were secured a few yards from the road.

At my request, Dr. P. M. Carrington of the United States Public Health Service, sent to me from Fort Stanton, New Mexico, a splendid assortment of the foliage of the grasses and stunted trees that grow with some difficulty on the dry plateau on which the national reservation is situated. The collection included specimens of alfalfa, loco-weed, scrub oak, cedar, salt-grass, blue-grass, blue gramma-grass, cottonwood and holly. The specimens were gathered with sterile instruments and expressed to me in sterile sealed tubes. From all of the grasses and foliage, only spore-bearing bacilli of various kinds grew. From the roots of several of the grasses to which bits of soil adhered, colonies

*Presidential Address to the Connecticut State Medical Society; delivered at the annual meeting in Hartford, May 20, 1915.

of cocci grew in greater numbers than colonies of spore bacilli. Plantings of various kinds of sea grasses growing on the shores of both sides of Long Island Sound, gave only spore-bearing bacilli if the specimens were gathered from clean rocks or sand, and gave admixtures of coccal colonies if the specimens came from plants that were muddied or that were submerged at high tide. Some beautiful specimens, gathered on the Long Island shore at a spot where they grew always under water on a clean white beach, gave only pure cultures of spore-bearing bacilli.

Where Spore-Bearing Bacilli Are Not Found.—For the purpose of my argument it is also important to know whether there are places in nature entirely free of spore-bearing bacilli. I intend to claim now that there are such places. Of course, I admit immediately that in most places of the earth there is a mixture of spore-bearing bacilli and the other forms of bacterial life. These mixtures occur in the soil, in water, in all decaying vegetable matter, in milk and other exposed albuminous or sweet fluids, in street dust and in house dust.

Where, then, are they not found? During the past twenty years I have examined, microscopically, many thousand specimens of human sputum. Except in the cases of a few patients who were sleeping out of doors among pines and firs in the coldest week of an Adirondack winter, I have never found spores in a specimen of sputum. Strange to say—and important to note—in one batch of specimens raised by these pine-wood patients after the coldest night of the year, when the temperature had been between 40 and 50 deg. below zero, I was able to grow from two specimens, a spore-bearing bacillus of the same general character as the spore-bearing bacillus that grew from the green needles on the neighboring trees. And, occasionally, in cases of chronic bronchitis I have grown from the sputum a large yeastoid bacillus, having many of the cultural characteristics of *Bacillus anthracis*. I have never seen a case of "wool sorter's disease." Of course, in that disease, *Bacillus anthracis* is found in the air passages. But with these exceptions, I have never seen a spore in human sputum, tuberculous or not, and, in spite of many hundreds of cultures made from all kinds of human sputum, I have never been able to grow from sputum spore-bearing bacilli in any kind of culture media, solid or fluid.

My experience, therefore, and it has been considerable, seems to justify me in saying that spore-bearing bacilli are not found in the healthy human air passages, and only very, very exceptionally found in diseased air passages.

No Spore-Bearing Bacilli on Healthy Human Skin.—During the last fifteen years I have had occasion to make bacterial cultures from various parts of the body, from all sorts of people. I have never been able to find a spore-bearing bacillus on the surface of the skin nor to grow any spore-bearers from the skin, from cerumen, from smegma, from the oral or nasal mucous membrane, nor—and I say this with hesitation—nor, from the human hair. In the food tract, however, the spore-bearers persist, and they can be easily grown from the contents of the bowels.

The facility with which cultures of cocci can be made from the skin and the mucous membranes of the upper air passages, and from sputum and from purulent discharges of all kinds, makes this absence of all spore-bearing bacilli from the human skin worthy of attention. Certainly every wind that blows, whether dust-laden or not, sprinkles the human skin with spore-bearing bacilli. What happens to these hardiest of bacteria that are continually deposited on the human skin? Of course, bacterial forms, other than cocci, are found on the human skin and in human sputum in health and in disease, but even they fit readily into the theory that they came originally from the spore-bearing bacilli. These are the diphtheroid and the acid-fast bacilli that are found in smegma and cerumen, in the accumulated oily sweat of arm-pits and groins, and in ozenal crusts. They are evidently transition forms; they do not preserve their acid-fast character, and frequently not their bacillary form on subculture. Very instructive also are the bacteria I have found in severe cases of chronic psoriasis. Some of them were perfectly acid-fast and resembled thick granular tubercle bacilli, but like some of the growths in smegma, they varied in acid resistance. Some of the rods had none at all, and mixed with them were cocci of the same size and staining as the coccal granules in the bacilli. Attempts at culturing these psoriasis bacteria resulted only in growths of cocci.

Now it was only at last year's meeting of this society that I exhibited pure cultures of acid-fast bacilli simulating tubercle bacilli, that I developed from old acid-fast spores of the hay bacillus—*Bacillus subtilis*. And in the hair the bacteria that I have found have been diphtheroid bacilli and cocci, sometimes in short chains.

Of course, I don't even insinuate that the partly acid-fast bacilli cause psoriasis any more than I would claim that smegma bacilli cause smegma, or that the acid-fasts of the oily secretion of an axilla caused the oily secretion. The simple explanation is that the cells of the skin, though increased in number, were so weakened with disease that they could not finish the breaking up of the bacilli or their spores, and the bacilli and spores therefore grew on the skin in this transitional form.

That the smegma bacillus may have an importance not usually ascribed to it, I have indicated in a little paper published by the *Lancet* in November, 1913, in which I told of a case of pulmonary tuberculosis following an infection by smegma bacilli. The histories of women patients at the State tuberculosis sanatoria reveal a surprisingly large number of cases of consumption, whose first symptoms were in the uterus, tubes, or ovaries.

I have noted that it is with hesitation that I speak of the human hair as being free from spore-bearing bacilli. I can only say that such has been the result of my experiments, but my experiments have been too few and have been mostly with tuberculous patients, and I do not feel that I have the same right to speak with certainty on this matter as I have concerning the flora of the air passages and the skin. But even if further experiment only shows that very rarely are spore-bearing bacilli found in the hair, what a tremendous digesting or transforming power the hair must have! And the cells of the intact human skin, and the mucous membrane of the air passages, do they digest or transform the spore-bearing bacilli? Or are the cocci that abound on skin the result of an action similar to Pfeiffer's reaction in which cholera vibrios and typhoid bacilli are transformed into coccal forms in the peritoneal fluid of injected guinea pigs?

Can Bacteria Change Form?—Because this is an annual address and is therefore protected from the critical discussion that perhaps many of my hearers feel it deserves, I will abstain from going deeply into this fascinating subject of the varying morphology of bacteria. But at least I may refer to my papers on this subject before the International Tuberculosis Conferences of Philadelphia, Brussels, (MEDICAL RECORD, Nov. 12, 1910), and Berlin (MEDICAL RECORD, Dec. 27, 1913), in which I tell (1) of breaking up spores of the subtilis into cocci by culturing them in various strengths of salt water, and (2) of forcing even tubercle bacilli to elongate, become granular, and finally extrude these granules as culturable cocci.

I must be permitted also to refer to Much's demonstration of a coccal prebacillary form of the tubercle bacillus, to Noguchi's making bacillus bifidus alternately spore-bearing and non-spore-bearing by changing its culturable environment. Of course, it is very remarkable to note the fixed characters that so many of the bacterial cultures in our laboratories preserve, and it is pleasant and restful to think that in nature they also always retain these characters, but the conditions in the laboratory test tube, and the conditions in nature are widely different. In the test tube the bacillus grows within a carefully regulated temperature range on a specially favored medium from which all other bacterial life has been rigidly excluded. In nature, it is needless to say, these conditions are impossible to find. Every breeze that blows makes a hopeless mixing of the bacterial forms within its reach, and changes the gaseous environment even of those forms that it does not move.

Is the Subject Important?—Perhaps you feel like asking where does all this lead to? What difference does it make to the Connecticut Medical Society whether or not the harmless spore-bearing bacillus is the only form of bacterial life in the clean places of the earth? What difference does it make to us that there are to be found no innocent spore-bearing bacilli on our skin or in our lungs? What difference does it make to us whether the spore-bearing bacilli that we inhale or that fall on our skin, die of fright and melt away, or are broken up into cocci by our defensive epithelium? What difference does it make to us whether smegma bacilli come from *Bacillus subtilis* or not; or whether smegma bacilli may become pathogenic, and after some period of incubation in the cells of the human being, acquire the power to cause tuberculosis in the lungs or elsewhere?

Well, you will find your own answer to some of these questions if you take stock for a moment of what your present bacterial faith is. Is it not this? "The unicellular vegetable organisms called bacteria consist of many thousands of species, some harmless to man and some harmful. These species, like the species of fish that swim in the sea, are distinct in character and origin. The staphylococcus must have come from another staphylococcus, the streptococcus from another streptococcus, the diphtheria bacillus from another diphtheria bacillus, the plague bacillus from another plague bacillus, the tubercle bacillus from another tubercle bacillus, and so on to the end."

It is on this conception of the origin of bacteria that all modern hygienic efforts are based. It is because of this conception of bacterial life that so many enthusiastic tuberculosis workers promise, by segregation, to rid their communities of the disease within a specified number of years, sometimes ten, sometimes fifty. But what becomes of your old faith if the innocent *Bacillus subtilis* may on greasy human skin become the harmless smegma bacillus, and if the harmless smegma bacillus may learn to live in human cells and later to destroy them and cause tuberculosis?

How false is the hope you give to the public about eradicating tuberculosis if you bend all your energies and theirs toward isolating the sick. Of course, the most stupid fruit dealer knows that he must remove the spoiled apples in a barrel in order to save the others. But the real apple problem, as our Mr. Hale and the other scientific orcharists have shown, is to learn how to grow and market all our apples sound.

Ten years ago when I began to claim that by changing the degree of saltiness or sweetness of culture media I could profoundly alter the characteristics of various bacteria, it was difficult to get a hearing, but now no such difficulty is encountered. The general principle is accepted and forms the incentive of research work everywhere. To-day, however, I want to keep your attention fixed on conditions that exist in nature, not on those of the laboratory. And to return to the problem of the disappearance of spore-bearing bacilli from the human skin, it ought in fairness to be said that the text-book explanation of this disappearance would be that as the spore-bearing bacilli did not find a suitable environment on the skin or in the throat or lungs, they died promptly and vanished. This explanation will not hold because spore-bearing bacilli are the most resistant germs of which we have knowledge, and because if they did die, they could not vanish unless you attribute a tremendous digestive power to the superficial epithelial cells. And if you concede such a faculty to these cells, you make simple the other explanation that these cells dissolve the shell of the spore-bearing bacilli and release as cocci their contained vital granules.

If this possibility be granted, it makes doubly interesting the recent researches showing that tuberculosis is a family disease. The tubercle bacillus is very sensitive to its environment. I have some strains that formerly grew well on glycerin-agar and on blood serum but after growing luxuriantly for one or more years on glycerin-broth-potato, they cannot now be induced to grow in their former favorite media of glycerin-agar or blood serum. It is easy to understand, therefore, that the tubercle bacilli that have been evolved from smegma bacilli in a father or mother after long struggles with the weakening lytic power of that father's or mother's cells, would be much more dangerous to the children of that father or mother, than to the children of any other father or mother, even though living in the same intimacy.

Such a theory would also explain the surprising immunity of so many husbands and wives of consumptives. At the New England Conference on Tuberculosis last October I asked whether any of the distinguished authorities present knew of a case in which they had been convinced from personal investigation that a negro man or woman had taken tuberculosis from a white man or woman; or of a case of a white man or woman that had taken tuberculosis from a negro man or woman; or of a case in which a parent had taken tuberculosis from its young child. There was considerable surprise at the asking of the question, but there were no

affirmative answers. I don't say that such cases may not occur, but I know of none and I think they must be very rare.

The Origin of the Pneumococcus.—Let us go back to the always-present cocci of the skin and air passages: if they are derived from the harmless spore-bearing bacilli of the air and leaves, is it not easy to understand why they are harmless on the intact skin, but become harmful when they have lived for a few generations, or seventy-two hours, in the broken cells and effused blood of an injured arm or leg? And does not this conception afford a new and inviting lead into the mysterious problem of pneumonia—traumatic pneumonia, epidemic pneumonia, and tuberculous pneumonia? For what is the cause of pneumonia? It's usually a coccus that is found frequently in the mouth vegetating harmlessly, but that from the beginning to the end of cold weather is our most dangerous foe.

In warm weather, the atmospheric conditions are so favorable that the spore-bearing bacillus grows readily in nature in its bacillary form, and when taken into the air passages, it is easily and quickly broken into its coccal granules. These resulting cocci inherit from their mother rod only a very thin shell which is easily dissolved by the cells and fluids of the air passages. They are incapable of penetrating even the weakest epithelium. In summer men have injuries to the chest; they get chilled in the water of the river or ocean, but unless they are very old or have tuberculosis, they seldom have pneumonia.

Now what happens in winter in the pneumonia months? The spore-bearing bacilli of the street dust and even of the bare trees have long ago lost their vegetative bacillary form and have all turned to spores and the capsules of these spores have become thicker and more resistant and often acid-fast. When the snow is on them, no matter how cold the weather is, there is little pneumonia in the community, but if the streets and the fields are bare and the weather cold, and the winds high, in other words, if it is a green Christmas, the hardy spores of subtilis or some of its kindred spore-bearers are inhaled with every breath by young and old. The cells and secretions of the air passages break up the spores as they did the rods in the summer, but the resulting cocci inherit now a thick capsule like the shell of the tubercle bacillus, and this is not easily dissolved even by the most vigorous epithelium. And in the weak and the aged and even in the young and strong who have by exposure, or by over-eating, or over-drinking, or excesses of any kind, caused a little congestion of the blood vessels of the air passages, these capsuled cocci gain access to the circulation and in a few hours there is another case of pneumonia.

In tuberculous pneumonia the development of the acute process may be explained in the same way except that the pneumococcus could come from the disintegrating tubercle bacillus. A few winters ago I had a very severe epidemic of pneumonia in the Home for the Aged in New Haven. Every day for a couple of weeks, on the women's side of the institution, one or two new cases of pneumonia broke out. And the cases were very severe. And all this while there were no cases of pneumonia on the men's side of the institution. At about the tenth day, I discovered that one fussy old lady who coughed but said she was not sick, had a chronic tuberculous process of the lungs. It was against the rule of the institution to harbor tuberculous patients. She was isolated and, after a few days, sent home. Not another case of pneumonia occurred. We found then that all the first cases were the women who were her chums, or who sat with her at table, or who slept beside her in the dormitory. Her sputum injected into a rabbit killed it promptly and filled its blood with pneumococci. She herself died in a few weeks rather suddenly.

A Tree and a Man.—In conclusion, in order to visualize quickly some of the points I have tried to make in this address, imagine what would happen to a young germ-free man and a young germ-free tree suddenly placed on the germ-free soil of a mountain top. The winds from the neighboring mountains or valleys would sprinkle both the man and the tree with spore-bearing bacilli. On the tree these spore-bearing bacilli would continue to grow as spore-bearing bacilli. On the skin of the man they would be promptly changed to cocci. Both tree and man would thrive. The leaves that fell to the ground would die. The spore-bearing bacilli would at first become spores. As the leaves accumulated the tendency to spore formation would slacken and soon, in the moist center of the heaps of leaves, only granular, non-spore-bearing bacilli would be found. As the leaves were ground into the soil, and the conflict between the tendency to spore formation and the tendency to normal vegetation became acute, the leaves would give off to the soil various kinds of cocci, and in places where the soggy earth covered some of the leaves and prevented access of air, some of the bacilli would be found that grew as rods, but with unripe spores at one end. These would be dangerous for the man for they would be the bacilli of tetanus. But like all the other derivatives of the original spore-bearing bacilli, they would be of benefit to the soil of the mountain top.

On the man the coccal forms would help in the exfoliation of the dead cells of his skin and mucous surfaces. They would pass into his food tract, produce acid, and assist in breaking up difficult food in his intestines. If the young man took no care to remove from his skin the matter that gathered there as the result of perspiration, there would appear in many parts of his skin, particularly on those parts where the exudation was heaviest and most oily, in addition to the always-present cocci, many short granular rods of which a certain proportion would be acid-fast, and would look like tubercle bacilli.

212 Orange Street.

THE AUTONOMOUS NERVOUS SYSTEM AND THE GASTROENTERIC FUNCTIONS.

By CHARLES SUMNER FISCHER, Ph.D., M.D.,

NEW YORK.

Whereas a schematization of autonomic nervous phenomena may beg for justification in the strictest physiological and pharmacological sense, an attempt toward such seems warranted in the light of recent developments. Common observation and experience amply teach that certain influences are at work producing fairly well-defined groups of gastric diseases. As in other special fields, gastroenteric cases follow certain tendencies among given peoples or communities, and that these tendencies are shaped by causes more or less inherent for these people, there can be no further doubt. There is sufficient clinical evidence to justify this assumption. These tendencies

deal with the fundamental etiological relationship of a great majority of our common dyspeptic disturbances. In the past, gastrological experiment and observation have dealt largely with final products. This concentration of attentive energy at one end of the line has resulted in a false etiological perspective, in that it has imposed undue emphasis upon a single phase of the whole subject. It has led to an enhancement of values of local conditions, oftentimes undue exaggeration of immediate defects, which, could they have been viewed in the light of an illuminating whole, would never have occurred. In this respect, gastrological science has suffered with all other newly developed fields. Had a proper appreciation of this entire department in its broadest biological aspects been possible earlier, many of the eccentricities of conception or superfluous manipulation would never have occurred. Any effort, then, however crude, which offers for its objective a philosophical reconstruction of this subject, should be beneficial, even if it is necessary for the accomplishment of such purpose to resort to a certain amount of strictly physiological and pharmacological liberal interpretation. Sufficient evidence has been produced to show that the autonomous nervous system plays a most important rôle, not only in inducing and instituting local gastroenteric functional defect, but also in controlling and shaping the course of such defect up to the point of profound organic change. Hence, it becomes almost imperative that a practical working knowledge of the anatomy, physiology, and pharmacology of this system should form part of the equipment of every intelligent gastrologist, not in the sense of a satisfying theoretical interest, but as an integral element in customary methodological practice.

For this purpose a certain anatomical visualization is not only desirable, but essential. Broadly stated, the anatomical plan of the autonomous nervous system is simpler than that of its antagonist, the sympathetic proper. It is demonstrably more intimately connected with the cerebrospinal system, its centers in the latter are more sharply defined, the course of its fibers more direct and continuous. Not only are the centers of the sympathetic proper in the cerebrospinal system still matters of speculation, but the course of the fibers themselves forms such a complicated network and their ending in the viscera is still so indefinite, that animal experimentation is forced to theorizing in regard to the results obtained. The interruption of the course of the fibers from central station to terminal station by two sets of ganglia further complicates the interpretation of the effects of stimulation, rendering them inconclusive in many instances. The autonomous system presents fewer difficulties in this regard. Here the centers in the cerebrospinal system are more clearly defined, the course of the fibers follows that of the latter, and no interruption in this course obscures the results obtained by the various tests. In this system the stations are located at the ends of the line, that is, in the central nervous system and in or near the viscera supplied. It is for this reason that experimental work has yielded more satisfactory results and given a much clearer conception of the condition known as vagotonia than corresponding work done upon the sympathetic proper. Whereas vagotonia appears to be justified as a clinical entity, sympathicotonia can only be regarded as highly probable by deduction. As interest in the present discussion is confined mainly to the gastrointestinal tract, only that portion of the autonomous system will be given which deals directly with the digestive functions.

The central stations for the autonomous system are located at the extreme ends of the spinal cord, those at the upper end being located in the floors of the third and fourth ventricles, and those at the lower end in the lumbosacral segment of the cord. From these centers the fibers pass by comparatively few routes to the terminal stations in or near the organs served. In the case of the digestive tract these are represented by the plexuses of Auerbach and Meissner, which latter have been dignified by Langley into a separate system, called the enteric system on account of their more or less well established autonomy. Hence, impulses originating in the central stations pass by direct routes to the organs and their effects upon these organs will depend upon the inherent receptivity of these organs or the plexuses located immediately within their structures. This is a matter of some practical importance, as will be seen later.

Practical gastroenterology is interested mainly in those nerves supplying the alimentary tract, those to the salivary glands, those to esophagus, stomach, and small intestines, and those to the colon and rectum. The salivary glands are served by the chorda tympani and autonomous fibers accompanying the facial and glossopharyngeal nerves. The chorda tympani arises in the medulla, close to the vagus center, and supplies the submaxillary and sublingual glands, passing by way of the facial and lingual nerves. It also regulates the vasodilator structures of the oral cavity. The parotid gland is supplied by autonomous fibers accompanying the auriculotemporal branch of the fifth nerve through Jacobson's nerve into the glossopharyngeal nerve. These fibers, dilator in effect, further supply the mucous membrane of the nose and pharynx.

The second and principal pair of autonomous nerves comprises the vagus system. They arise in their known centers in the medulla and supply the lower esophagus, stomach, with sphincters, small intestines, pancreas and liver with ducts, and kidneys. The vast amount of experimental work done upon this system with regard to gastrointestinal secretion and motility has served well to inculcate this as a universal conception. Its relation to these functions is fully described in all textbooks. On account of the vastness of the territory covered and the intricacy of interorganic connection, the possibility for reflex phenomena are enormous, and in this regard it should be intimately understood. For this purpose, it is pointed out and emphasized that the centers for the chorda, tympani, facialis, glossopharyngeal, and spinal accessory nerves are closely related to those of the vagus system in the grey matter beneath the aqueduct of Sylvius where it enlarges to form the third ventricle and in the floor of the fourth ventricle. From these closely associated origins the three nerves, glossopharyngeal, spinal accessory, and vagus, pass through the jugular foramen, to be distributed to the various structures. In passing through this opening the vagus presents an enlargement called the root ganglion. This ganglion receives fibers from the accessory portion of the spinal accessory and from the glossopharyngeal nerves, and is connected with the facial and superior cervical sympathetic ganglion by means of an ascending filament. Immediately after emerging from the jugular foramen the vagus presents another ganglion, the trunk ganglion, which receives filaments from the hypoglossal nerve

and the superior cervical ganglion. From here on the fibers of the vagus pursue a comparatively uninterrupted course to the viscera. On account of the possibility for reflex, certain of these fibers possess special interest for the gastrologist. These are the cardiac and pulmonary and gastric fibers. Reference need only be made to the frequency of dyspeptic asthma, cardiac irregularities, and the occasional attacks of so-called acute indigestion with fatal termination. The right vagus supplies the posterior portion of the esophagus, the posterior surface of the stomach, and joins with the cardiac plexus of the sympathetic proper. The left vagus supplies the anterior portion of the esophagus, the anterior surface of the stomach with its lesser curvature, and joins with the hepatic sympathetic plexus. The final stations for the vagus lie in the viscera themselves. Here the fibers are split into those going to the serosa, forming a network upon its surface and those penetrating the structures to terminate in the plexus of Auerbach and Meissner. The influence of the vagus system decreases from oral cavity downward. In the lower abdomen its functions are taken over by the pelvic nerve. This arises in the sacral segment of the spinal cord, passes without interruption to the pelvic ganglion, from which it supplies the colon, sigmoid flexure, rectum, and anus.

This comparatively simple anatomical plan of the autonomous system renders its visualization for practical purposes fairly clear. It is possible to carry the picture in mind without special effort of memory or imagination. There is a possible grouping which may be convenient, namely, that of chorda tympani and glossopharyngeals for the oral structures, vagi for the alimentary tract from pharynx to colon, pelvic nerves for the lower abdominal viscera. The vago-glossopharyngeal-spinal accessory anastomotic complex at the jugular foramen is specially important. Not a day's work passes in gastrology but signs or symptoms of reflex involvement of this network of fibers present themselves, the only explanation for which may be found in the interplay made possible at this point. With the knowledge to hand impulses passing between the digestive organs and other structures may be traced with a fair degree of accuracy. Many obscure phenomena may be made to fit into the general scheme of a given case.

It must be remembered that such schematization as here presented rests entirely upon the anatomical conceptions of Langley. That these do not entirely agree with the pharmacological conceptions of Eppinger and Hess or Heubner is well known. Whichever may prove the correct ones in the course of time, there are sufficient observational data to warrant the assumption of a definite delimitation between autonomous and sympathetic systems, which can be employed for very practical purposes and which should be regarded as an important part of gastrological teaching.

The physiological effect of excessive autonomous control is manifested in innumerable signs and symptoms encountered in ordinary clinical work. Were it possible to have a condition in which this system, unopposed by sympathetic counteraction, gained complete mastery of function, the resulting activity would pass far beyond the necessities for life. With regard to the digestive tract, this excess would be apparent from mouth to anal ring. Whereas the sympathetic system proper is the great inhibitor, the autonomous system constitutes the general exciter of all the processes relied upon for nutritional reduction. In short, there would result universal hypersecretion, hypermotility, and hypersensitiveness. Practically, these conditions may present any modification as to regularity, continuity, or periodicity, but the principle is the same in all. Beginning with the mouth, every salivary gland would produce an excess of secretion, evidenced clinically by salivation, with or without ptyalin activity and easily influenced by sight, odor, or touch of food. There would further be present an irritability of the pharynx with tendency to excessive gag reflex and nausea, faucial hyperesthesia with constriction, spasm, and globus. The esophagus would exhibit a condition of resistance to passage of food or the tube, with sensations of tension and pressure behind the sternum. The cardiac orifice of the stomach would be in a state of continuous or remittent spasm resulting in obstruction with esophageal dilatation, deceptive sensation of fictitious gas accumulation in stomach, with difficult eructation and danger of acquired aërophagic habit, and attacks of acute cardialgia. The clinical possibilities of the stomach itself loom large. With the enforced excess of acid they would include the whole range of the variously described pathological, hypersecretory states, permanent, temporary, periodic, capricious, alimentary, or larvated, the specific nature of each being determined by fortuitous circumstances, either local or general, existent at the time. There would exist the same possibility for diversity in the motor sphere, including simple hypermotility, either direct or reverse, tonic contractions exhibited as cardiospasm, gastrospasm, or pylorospasm, insufficient relaxation after food intake, producing sensations of fictitious fullness, painful contractions due to premature emptiness. The etiological importance of these activities for later organic defects is obvious. Especially is this true of the continuous or frequent spasm of the sphincters. Such spasm may extend to the gall ducts simulating hepatic colic or resulting in temporary retentive icterus.

Both the secretory and motor activity of the small intestines would be increased. This would result in painful hyperperistalsis, intestinal unrest with excessive borborygmus, visceral hyperemia with depressing postprandial drowsiness, serous diarrhea, occurring at times with great suddenness, usually however, immediately after meals or in the early morning. The signs of autonomous hyperactivity are especially marked in the large intestine. As secretory disturbances there would be intense antiperistalsis in the ascending colon, diarrhea, with rapid fermentation, mucous colitis. The motor activities are manifested principally in the descending colon and rectum. There would be a frequent desire for stool, rectal pressure, pencil formation of excreta or small, unsatisfactory movements, spastic constipation, proctospasm. As the vasomotor structures of the abdominal viscera are under the control of the sympathetic proper, any disturbances in this field accredited to autonomic influence, must be largely relative. Here autonomic hyperstimulation postulates sympathetic depression. Hence, if sympathetic hyperactivity produces vasoconstriction, vagotonus must cause the opposite effect or vasodilatation, and we should have all the various evidences of abdominal plethora, hemorrhoidal fullness, portal and hepatic congestion, etc.

Not the least interesting or important feature in connection with autonomic hyperactivity is the facility with which the reflex interplay between the various abdominal organs is rendered possible. From a practical standpoint, a knowledge of this action

often becomes a matter of serious diagnostic concern. The comparatively simple anatomical plan of the autonomous system lends itself very readily to such organic interaction, and renders such action more readily comprehensible. The secretory function of the stomach appears to be especially prone to this influence. Distant abnormal states of the colon, genitals, appendix, hepatic or renal calculi, ptoses of all degrees and kinds reflect themselves in secretory gastric disturbances, the immediate nature of which depends upon local receptivity, susceptibility, or defect. That in the majority of cases there should be exhibited an excess of functional activity, resulting in the various hyperacidities, may be due in large measure to the guiding autonomous control itself. Given, a normal stomach, any reflex delivered through the vagus must result in excess of functional, secretory activity, not only upon strictly anatomical or physiological grounds, but also, it may be due to a general biological, inherent tendency. This latter offers a problem for considerable interesting speculation and deduction, which is also not without a certain practical bearing. The acid secretion of the stomach is in the last biological analysis—a defensive and self-sustaining reaction resulting from the evolutionary development of the original cell. The original cell digested its enemies. Hence, the oxyntic cell unit in the gastric mucosa responds to irritation by secretion of its digestive defence reagent, hydrochloric acid. Zoology offers many examples of such defensive secretions. Being a product of cell decomposition, these secretions are usually self limiting in the sense that such decomposition products react as poisons upon the producing cells themselves. The yeast plant will produce alcohol only up to a certain concentration. The same principle holds true for the gastric secretion, except that here the coexistent hypermotility, also of autonomous origin, sweeps away the excess acid, and it is not until an interfering duodenal reflex, resulting in pyloric spasm, blocks the passage,—that all the various retentive disturbances begin. Thus is presented an anomalous physiological activity, namely, hypermotility to distribute the acid excess and, due to the same influence, pyloric spasm to block its passage. Hence, the two states, hyperacidity and hypermotility, bear a very definite physiological, anatomical and biological relation to each other, which must be given due consideration in the judgment of these conditions. This can be done many times by a thorough investigation of the autonomous, nervous control regulating the functions themselves. Given such knowledge, many cases will yield to treatment directed not against the local manifestations, but against the guiding influence inducing these manifestations.

The stomach may not only be the receptor for reflex influences; it may also originate and pass on such influences to other organs. It must again be noted in this connection that the vagus influence gradually diminishes from the mouth downward, and that the direction of increasing force of impulse is always toward the central station. Hence, as a receptor of reflex influences, the stomach is mostly concerned with the structures near or below it. As an originator of such influences, it passes them on to the structures nearer the centre, in this case the thorax. The vagus distribution to mouth, neck, thorax, and stomach is close. Not only are the centres for the glossopharyngeal, spinal accessory, and vagus intimately associated in the floor of the fourth ventricle, but the latter nerve in passing through the jugular foramen receives filaments from these nerves and also from the hypoglossal, facial, and superior cervical sympathetic. It is for this reason that thorax-complicatory symptoms so often accompany organic gastric conditions. Here belong bradycardia, cardiac arrythmia, dyspeptic asthma, vertigo, false angina, constriction of fauces, and dyspnea. These conditions may not only be annoying, but oftentimes they are misleading and dangerous. They are deceptive, in that many times there exists no quantitative relation between the gastric lesion and the induced reflex. The severity of the latter may obscure the producing cause, which may even be of minor degree. This discrepancy between local change and the distant reflex intensity, is due many times to an exaggerated reactibility of the autonomous system, and it is only by a careful investigation of the latter that misconceptions may be avoided.

The clinical importance of autonomous influence upon the gastroenteric motor functions, has been emphasized and delevoped by von Bergmann and his associates. By a happy combination of pharmacology, Roentgen rays, and abdominal fenestration, these observers have been able to demonstrate, beyond reasonable doubt, the very decided effects of exaggerated or diminished control of this system. They have indicated the etiological importance of this control for possible future organic changes. Their work deals largely with the ultimate results of cardiospasm, gastro-spasm, and pylorospasm. These are final states. Before they are reached, however, there are always minor evidences of exaggerated autonomic control which indicate the tendency of the individual disposition, and the end toward which he is progressing. These lesser evils are the common property of an innumerable number of dyspeptics, and their importance for diagnostic survey is usually neglected. Whereas cardiospasm and pylorospasm are comparatively rare, these apparently unimportant local discomforts are so common, that they fail to impress on account of this very character. Daily routine clinical work encounters individuals with fleeting gastralgias, facile epigastric shock, insufficient local relaxation following food ingestion, rapid satiety, oppression in epigastrium suggesting gas accumulation, feeling of constriction around waist, emptiness shortly after meals, annoying gastric or intestinal unrest, excessive postprandial drowsiness. If, in such cases, the chemical and physical examinations reveal certain functional dyscrasias, the natural tendency would be to concentrate attention upon these, when in truth, the cause for the whole condition lies in a constitutional defect, which, if not realized or counteracted, may lead on to the graver forms of local changes. Careful and comprehensive etiological inquiry into the previous histories of such final states as the Reichman syndrome, benign obstructions wherever located, many gastric or duodenal ulcers, would develop the conviction that the tendencies to these conditions were inherent in the individual from the beginning, as evidenced by the continuous presence of one or more of the minor disturbances of digestive comfort stated. As Rössle very properly remarks, "It is the disposition which counts," and it is in the determination of this disposition that a correct valuation placed upon the always present and usually neglected dyspeptic commonplaces counts for much. The usual habit has been to regard these ordinary symptoms as indications of local changes, when in reality, many of

them existed long before any local changes were manifested. Viewed in this light, the latter would constitute what Rössle again calls the second disease (zweitekrankheit), giving, as it were, two fairly well-defined aspects to every chronic gastroenteric problem,—the constitutional aspect or primary disease, and the local aspect or secondary disease. In order to place upon the former an intelligent estimate, and to give it a practical bearing upon any given case, a keen analysis of the reactional vegetative nervous trend of the individual is demanded, for whatever may be the various controversial questions of anatomical or pharmacological differentiation, or the undecided problems of specific drug reaction connected with the vegetative system, clinical experience demonstrates that many individuals, under the ordinary conditions of modern life, do exhibit a disordered state of equilibrium between sympathetic and autonomous activity. The habit to investigate these systems should form a customary procedure in every case, for without the knowledge thus acquired, any conception must be incomplete.

Whereas the evidences of excessive sympathetic control may be said to indicate a general apathism, those of excessive autonomic control would represent a condition of erythism. For the practical purpose of rapid, clinical orientation, the latter may be roughly divided into superficial or cutaneous and the deep or organic. Such division must of necessity be more or less arbitrary, running counter to some mooted questions of anatomy and physiology. Nevertheless, such schematization offers to the clinician certain landmarks which may serve to arouse the suspicion of the tendency of any given case. With this end in view, the attention should be arrested by such superficial signs as excessive blushing, mottling of the skin, dermographia, seborrhoea, factitious urticaria, excessive perspiration with moist and clammy hands and feet, myopia, epiphora, very bright eyes, muscular fibrillation, twitching of eyelids, very fine hair, easy loss of hair, early gray hair, early caries of teeth, excessive salivation, facile spasm of pharynx and esophagus, globus. The presence of any of these signs markedly developed, should lead to the search for others.

The deep signs of excessive automatic control may be subdivided into circulatory and organic. Among the former may be mentioned a slow or irregular pulse, deficient distal circulation, head pressure symptoms due to this, transient low blood pressure, palpitation, bradycardia. The organic signs would include temporary, defective accommodation, contracted pupil, neuromuscular spasms, pain in back of neck, morning headaches, precordial pains, transitory tendencies to icterus, asthma, gastralgias, intestinal or hepatic colics, spasmodic bladder seizures with interrupted end urination.

The elicitation of most of these signs generally is a matter of casual observation. Usually they are overlooked or at best considered apart from the principal trouble. They may be emphasized as distinct disturbances or they may appear in a certain combination. Occasionally the individual attention is directed to some one particularly annoying or distressing. If one is present, there usually are others to be found. A systematic search should be made in every case, for it is the apparent insignificance of these signs which is misleading. It may appear to be a far cry from a blush to a pyloric spasm, and yet both may be determined by the same underlying cause. A constantly present spasmodic resistance to the passage of the stomach tube might lead one to suspect that perhaps the pylorus may be acting in the same manner.

There are certain physical procedures which may help and should constitute part of every routine examination. One of these refers to dermographia or vasomotor after blushing (Polonsky). Gentle stroking of the surface of the abdomen with the finger nail will be followed in a few seconds by dilation of the cutaneous vessels, resulting in anything from simple suffusion at the point of contact to the production of actual wheals. The intensity of the reaction is indicative of the extent of the loss of normal vegetative equilibrium. It is present in both functional and organic nervous conditions, suggesting that it may be of central nervous origin. Of its value as a hint, there can be no doubt.

Another indication of autonomic irritability, especially cardiac vagus instability, is the so-called respiratory arrhythmia (Hernig-Lommel). In this phenomenon, the pulse is momentarily accelerated during full inspiration, becomes markedly slow if the breath be held, to suddenly quicken again upon expiration. To a certain degree, it is normal in all individuals, but its exaggeration is evidence of "excessive sensitiveness of the cardioinhibitory vagus centre." Section of both vagi eliminates the phenomenon, as does also atropin.

A third physical test is represented in the bulbar pressure phenomenon (Aschner). In this test gentle pressure exerted upon the eyeball produces slowing of the pulse and respiratory rate, which may extend to pronounced bradycardia. It is caused by a reflex from the first branch of the trigeminus. The test is ineffective in normal individuals, but may be prominently responded to in the neuroses and vagotonia. The same reflex may be induced from the nasal mucous membrane by tobacco fumes and ammonia. The pulse rate may be reduced to forty per minute. The positive issue is always pathological, and according to Aschner, would indicate the close biological relationship existing between the vagus and trigeminal nerves.

Further simple tests may be made by plunging one hand into ice water. In case of excessive vasomotor irritability, the other hand will respond by dilatation of its cutaneous vessels, amounting, in some instances, to cyanosis. Attention should also be directed to the tendon reflexes. These should be investigated in every case, for oftentimes they may give some hint as to general irritability of the entire nervous organization.

Having determined the reaction of the autonomous system by these simple procedures, there still remain certain of the pharmacological tests. These have been the subject of much dispute. The results obtained by experiment have never been conclusive in a strictly anatomical sense, the indications at present being that the agents employed may, under certain circumstances, be reactive for both systems. Nevertheless, enough has been accomplished to demonstrate with some assurance, that there is a distinct group of substances whose influence is preponderantly autonomous and whose effect upon this system may be employed for diagnostic purposes. This can be attested by clinical experience. If, as Fröhlich and Loewi assert, the autonomous system contains both stimulating and inhibitory fibers, the former so far outclass the latter in importance, that for practical purposes the latter can be ignored.

In the present state of knowledge the human organism contains no native "autonomin" which may be opposed to the native adrenalin of the sympa-

thetic system. All efforts to produce such a substance have failed thus far. The nearest approach to it would be an aminoacid base, the result of intestinal decomposition. Hence, experiment has dealt largely with foreign poisons. If the sympathetic system proper may be called the adrenalin system, the autonomous may be designated as the cholin system, for it is the group of chemical agents represented by the latter which directly affect this system. This group includes cholin, muscarin, and physostigmine, substances which have proved themselves too violent for ordinary use. In the drugs pilocarpine and atropine, however, we possess autonomous agents which have shown themselves of great usefulness for this purpose, both from a clinical and experimental standpoint.

According to Eppinger and Hess the hypodermic injection of 0.01 grms. of pilocarpine hydrochloride will produce in the hypersensitive autonomic disposition a group of symptoms exhibited as salivation, hyperchlorhydria, cardiac and pyloric spasms, spastic constipation, slow pulse, low blood pressure, respiratory arrythmia, asthma, epiphoria, dermographism. However true this extensive presentation may be as a whole, the clinical fact undoubtedly exists that individuals suffering from any of these symptoms or a combination of them, bear pilocarpine medication, in any form, very badly. This is especially so for the digestive system, and the drug has been to a certain extent, employed to stimulate decreased functional activity for a considerable time. That it has not been more extensively used is probably due to the disagreeable side effects, for the investigations of Katsch have demonstrated that while pilocarpine does in effect stimulate, for instance, the motor function of the intestine, it does so in an irregular, unphysiological manner, which vitiates in a large measure its therapeutic value. Where, however, the question at issue is the determination of the reactional trend of the autonomous system, the use of this agent as test may be of considerable advantage. The hypodermic is not necessary. Given by the mouth in the usual doses, its effect will soon be apparent.

The greatest service in the determination of the vagotonic disposition has been rendered by atropin. While the effect of this drug may be still questioned in point of detail, there can be no doubt that as a paralyzer of excessive autonomic activity, it stands first. In very small doses in normal individuals it may at times act as a stimulant to Auerbach's plexus, but in full doses it will always allay excessive vagus irritability. In this regard it is invaluable for diagnostic purposes, whatever may be its action under other circumstances. As Hemmeter very properly contends, there are certain dispositions which respond equally to adrenalin, pilocarpine, or atropine the only conclusion to be drawn from this being that in such individuals the whole nervous system is in a state of instability. Such cases are sufficiently numerous. In many other cases, however, exhibiting gastroenteric hyperfunctionating activities, combined with any of the various stigmata enumerated above, pilocarpine will always aggravate and atropine allay the distress. Nor does the existence of demonstrable structural lesions in the tract vitiate this, for many of these local changes would pass unnoticed oftentimes, were it not for the coexisting general disposition. It may well be that the local defects are the direct result of long-standing functional dyscrasia or to a local defect, the result of some habitual fault, may be added independently the additional burdens here mentioned. This is abundantly revealed in those postoperative cases, where, notwithstanding that the structural changes have been remedied, the symptoms continue as before.

It must be evident that the time has come when a certain practical knowledge of the operations of the vegetative nervous system is absolutely essential for the proper valuation of the various alimentary disturbances, for it is this system which serves as the connecting link between a host of foreign influences which have a very direct bearing upon digestion. As Sherrington says, the environment drives the nervous system and the nervous system drives the entire organism. It is by no fortuitous circumstance that this system has been developed as it has. From the biological standpoint, it is the result of a gradual evolutional change for purposes of defence. It is an arrangement for adjustment to the environment in the sense of survival of the fittest and the digestive processes are in this conception but a part of such a scheme. In this adjustment the autonomous system plays a most important part, in that it acts as the essential stimulator to action. The unusual simplicity of its structural scheme renders it peculiarly useful in this respect. As has already been pointed out, its fibers pursue a comparatively uninterrupted course from central stations to the organs and the location of its nuclei well within the cerebrospinal system, close to the vital centers, renders it especially liable to the influences of the environment operating through consciousness. Hence, it is not surprising that in case of the digestive organs, the primary disturbances of functional activity should be those of excess, both secretory and motor, and that many of the late more distinctly localized gastrointestinal conditions are but crystallizations of these tendencies.

The error is usually made to demand for the condition vagotonia a distinct and pronounced symptom complex, as given by Eppinger and Hess, or as contained in the vasovagal attacks of Gowers. These states are comparatively rare, and having attained to such dignity, they dominate and obscure all local conditions. More interest for the gastrologist is attached to the reactibility of the autonomous system, its power to influence and direct functional activity over long periods of time. Under ordinary conditions of life, it may not be in evidence, but given the opportunity, under conditions of strain, it will immediately respond. In most cases, it is an inherited weakness, susceptibility, irritability, and constitutes what von Bergmann terms the disposition, not in the mental conception, of the individual. It is the primary disease of Rössle, and the directing influence which may lead ordinary gastrointestinal functional disturbances to distressing organic changes. While it has been especially emphasized by the latter as an important factor in the etiology and pathogenesis of ulcer, it constitutes, when present, a directing menace in all forms of acquired digestive disease. Viewed in this light its presence is ubiquitous and constitutes a very decided factor in the vast majority of the ordinary indefinite, mixed, and undeterminable cases of ordinary gastric disturbances, common to every clinic, for it is the connecting link between inherent organic weakness and whatever evil influences may exist in the life of the individual. The careful examination of most of these cases of indeterminate, chronic dyspepsia, will reveal the fact that they cannot be attributed to anything tangible in the way of definite abuse, but that

they can be traced back to that period of life when the responsibility of existence and maintenance began to exert itself. From this time on the inherent weakness or instability of the vegetative nervous system begins to affect those organs under its control which are most receptive. Why, in many individuals, this should be the stomach has already been discussed. In many cases it is a psychological problem. That this vagotonic disposition should be so frequent is not surprising. As the stimulator of all vegetative function its activity would be the first to respond to the general exciting and irritating conditions so prevalent at the time.

It is too late in the day to deny the enormous influence upon digestive function of factors operating through consciousness and subconsciousness. This has been thoroughly tested, both clinically and experimentally. The hysterical state will produce anything from cardiospasm or pylorospasm to gastrospasm with hourglass contraction or intestinal occlusion with fecal vomiting. Attention, however, can be directed to a certain misconception as to the operation upon the gastric function of the element of fear. It is generally assumed that the effect of fear upon digestion is inhibitive. This is based upon the construction placed upon the observations of the Roentgenologists. These experimentors were dealing with the element of fright. This psychologically is something entirely different from fear. An individual may not be frightened without fear. He can fear, however, without being frightened. Fright paralyzes all voluntary motor and vegetative functional activity. Fear may very well stimulate both, and usually does. What is operative in the lives of most individuals, under present conditions, is the element anxiety which may reveal itself as concentrated attention, hope, aggressiveness, determination to succeed. The examination of the gastric contents of the insane has yielded no very definite results. Where the rational connection between psyche and environment is severed, the analytical findings seem to be entirely dependent upon local material conditions. Where, however, the rational connection is preserved, as it is in most of the ordinary forms of the anxiety neuroses, then the phobia which is common to them all, stimulates to functional activity, not least among which are the digestive functions. These unavoidable factors of consciousness can only be operative through the vegetative nervous system, and their effect upon function will depend entirely upon the inherent organization of this system.

The study of the influence exerted by the vegetative nervous system has rendered possible a much broader conception of the whole subject of gastroenterology. It has shifted the interest from the narrow observation of local changes to a more intelligent interpretation of etiological relationship. It has introduced into the subject a certain purpose and design, traceable along biological and physiological lines. It has produced a new classification, in that it has eliminated individual judgment based upon the biased understanding of local conditions. The old conception of disorders of sensation, secretion, and motility, which only tabulates, and explains nothing, will yield to a classification based upon comprehensive pathogenesis. It will be more generally recognized that there are two phases to the great majority of our digestive diseases. One of these would embrace the constitutional trend of the individual conducive to the initial disorders of function. The other would include all the local changes following upon the prolonged existence of these primary functional disorders. It is the latter which has been exhaustively exploited in the past. It is the former which is going to command the attention of the future as the "primary disease." In every case of either hypo- or hyperfunctional activity, with or without structural change, more emphasis will be placed upon the influence which conduced to these changes. In a given case of hyperacidity and hypermotility, the search for enlightenment will not be limited to the possible existence of obstruction, dilatation, retention, and ulcer,—it will be demanded whether or not there had existed in that particular individual for years a mental state, vegetative nervous hypersensitiveness, local organic susceptibility, and a maladjustment of daily life of far greater diagnostic, prognostic, and therapeutic value than the local conditions themselves. Except in the minority of cases, where the evidence of habitual abuse, inflammatory change, or direct local influence is indisputable, the majority of the gastrointestinal disorders encountered in the day's work will bear close scrutiny along the lines indicated.

Every gastrointestinal disease possesses these aspects,—the purely local, the metabolistic, and the neurological. The last can again be subdivided into the distinctly psychical and the neurophysiological. It is the study of the neurophysiological which marks a decided advance, for it can be applied in very practical form with illuminating advantage to most of our digestive disturbances. What has already been said in regard to such common funcdifficulties of diagnosis, but it seems to be an extional changes as hypersecretion and hypermotility, will apply equally well to other conditions. In every case of suspected duodenal ulcer, inquiry will be directed to the primary disease, for, with the exception of the gross appearances of mechanical obstruction or hemorrhage of the last stages, every one of the so-called typical signs and symptoms, latency, periodicity, so-called hunger pains, and the excesses of function may be an inherent part of this primary disease without structural change, and may continue thus for years. It is true that the fluoroscope has, to a certain extent, obviated some of the pensive procedure, and is of service only in those cases where much local damage has already been done, and where the evidence is so marked that as a diagnostic method it can only be confimatory. It is a fairly safe assumption to make that with a systematic inculcation of this neurophysiological aspect into routine practical application, the exceeding prevalence of duodenal ulcer would be rapidly diminished. The greatest value, however, of such a conception does not lie in diagnosis, but in prognosis. Having determined the underlying constitutional trend primarily producing these symptoms, the individual can be warned against the possible final outcome, provided the tendency is not controlled or checked. It has been said that duodenal ulcer is a disease of modern life. This may well be true, for at no previous time has there been such a strain placed upon the mechanism which controls the local conditions productive of this state.

There has been a tendency in recent years to cast considerable doubt upon the validity of the average chemical findings in gastric analysis. To a very large extent this is justified. To jump to a diagnostic conclusion from the simple determination of the percentage composition of the gastric juice, or its volume, will oftentimes lead to error. The value

of the actual figures of an analysis will depend entirely upon the interpretation placed upon them. Such interpretation will, in turn, depend upon the comprehensive physiological, neurological, and psychological knowledge of the investigator. What constitutes a hyperchlorhydria for one individual may well be the normal acidity for another. There are no rules to determine this. It is an entirely individual matter. Nowhere is a more practical application of a comprehensive grasp of the reactional trends of the individual as evidenced in sympathetic or autonomous nervous phenomena, more possible than right here. In order to demonstrate the difficulties which the judgment of any given case of hypo- or hyperfunctional activity may encounter, it is only necessary to remember that such diversions from the normal mean may be dependent upon either purely local conditions, perverted or abnormal metabolism, or constitutional reactional trends. As a rule, the first two present no special difficulties. They are easily determined. When it comes to the last the situation becomes more complicated. Here it must be determined whether the fault lies in the irritability of the organic constitution of the nervous system or whether the psychic development is involved. Both require the keenest inspection. The simple diagnosis of neurasthenia or hysteria is not sufficient in this regard. The methods for the examination of the organic nervous control have been given. Where the psyche is contributing its share, the examination must be directed toward ferreting out the particular element in the mental life of the individual which is reacting upon the organic processes. This is oftentimes a matter of some difficulty, and may meet with opposition. Nevertheless, its elucidation at times becomes imperative.

From the foregoing, it is conceivable that any judgment of disturbed functional activity of the digestive tract, based upon simple analytical figures, must be exercised with considerable care. The conventional test meals are of service only in so far as they may be indicative of the actual power for secretion inherent in the local structures themselves, that is, the individual cells. They take no cognizance whatever of the influences at work directing these cells. Hence, these tests hold true only where the disfunctioning is the result of either immediate local structural changes or a weakness due to a general metabolistic process. Where, however, the local hypo- or hyperactivity is but a reflection of the influences exerted in the third category, the very artificial nature of the tests precludes their usefulness many times. In the latter case, it is far safer to accept the results obtained by analysis with a certain reserve, and with a view to orientation, and then when the individual has become thoroughly accustomed to the necessary manipulations, to base final judgment upon the effects produced by a meal of his own selection, corresponding as much as possible to routine daily habits in this regard. In this manner, many disturbing and disagreeable influences are eliminated, and a true insight is gained into the operation of the functions under conditions natural to the individual for his station in life. The divergence of results will often be surprising, and treatment based thereon most satisfactory.

These advantages accruing to the investigator of gastroenterological disturbances, of a practical conception of the operation of the vegetative nervous system, can be extended to include any question of diagnosis or prognosis which does not involve actual mechanical interference. The examples cited are typical. With such knowledge many abuses and fads would either be modified or eradicated. Not least among these would be the subject of autointoxication, that melting pot of insoluble problems. Before drawing precipitate conclusions in such cases, the reactionable tendency of this system should be definitely determined, not as to immediate instability, but as to its permanent constitution as an inherent part of the individuality. A certain quantity of noxious poison is developed in the course of all normal proteid digestion. To a certain degree this is always absorbed and successfully combated by the organism. Given, however, an irritable and susceptible sympathetic system, it may well be that even this unavoidable quantity will act as an irritant, producing the various well known effects usually ascribed to this condition. To diagnose such a state as autointoxication is manifestly an error, and to treat it as such by undue attention to the local conditions, can lead to no permanent relief. In all cases of this nature it becomes especially important to compare the extent of the local fermentative processes with the permanent and preexisting condition of the system first affected. If the latter be found to be defective in the constitutional sense, the diagnosis of autointoxication would become relatively insecure, and should receive only secondary consideration, for it may well be that whatever fermentation exists, would be well supported by an organism which was normal in tone and power of resistance. It is pretty safe to assume that were this aspect of the subject properly considered, the autointoxication fad would rapidly vanish.

Much importance in recent years has been attached to the power of reflex action. In abdominal diseases enthusiasm in this direction has run riot. Judged by the standards here given, this tendency would also be curbed, for it should be remembered in this connection that the possibility for reflex action to a distant part depends in the last analysis upon the conductibility of the connecting structures. If these are easily influenced, it is to be assumed that the organs, whose functions they control, would also be easily affected and a reflex action be initiated in the organ most inherently receptive for the individual. That, in most cases, this should be the stomach is not surprising. If, however, the conducting structures upon examination exhibit absolutely normal tone and reaction, the diagnosis of a reflex effect should be accepted with considerable reserve. Close inspection in most cases of this nature will usually reveal sufficient local reason for whatever disability may exist. Certain individuals are especially liable to reflexes of all kinds. They react excessively and many times by circuitous routes, to any exceptional influence of their environment. These individuals always possess defective sympathetic systems, and in every such case where the question of reflex action arises, this phase should be thoroughly investigated. This applies not only to the direct or unconditional reflexes, but very pertinently to what have been called by Pawlow, in his most recent work, the "conditional reflexes," those instituted by factors apparently entirely foreign to the particular function affected. These so-called conditional reflexes have received very scant clinical attention in gastroenterology, but that they play a most important part in the causation of digestive disturbances, future investigation will probably develop.

It would appear at first sight that emphasis such

as this, placed upon the practical investigation of the vegetative nervous system in all cases of gastro-intestinal disease, would be to attach undue and exaggerated importance to nervous phenomena in general. While such conditions do exercise an enormous influence in this class of cases, it is fully recognized that there is some danger that recourse to them for purposes of diagnosis may be overdone, especially in obscure conditions. This is especially true of the influence exhibited by the emotions. It is exactly to impose a curb upon such speculations and to place upon the effects produced a proper valuation, that a certain applicable knowledge of the structure and operation of the vegetative nervous system becomes eminently desirable. For this purpose some sort of schematization is necessary, even though compelled at times to make assumptions which are not entirely warranted by secure physiological and anatomical data. Whatever may be the changes in the details to be made necessary by future investigation, enough has been done to make a comprehensive and systematic conception of the whole possible. This tendency toward systematization is the last word of modern medicine, has largely eliminated the grab-bag of empiricism, and has raised the whole subject to the dignity of the exacter sciences. No average mind can master all the details of immunity, or the internal secretions, or the more recent physicistic conception of the circulation, but it can acquire a certain schematic grasp of these problems and employ them in whatever philosophical bearing they may have upon its own immediate work. This constitutes the intelligent practice of the day.

It is in this spirit that the whole plan of the vegetative nervous system should be conceived. In gastroenterology it enlarges the field of vision and delivers the subject from the narrow limits of immediacy. There is pretty good evidence that the local soil is becoming barren. To a certain extent this is an advantage and will serve to turn attention to the broader aspects involved. The opportunities here are enormous, for it can be repeated again with emphasis that the great majority of digestive disturbances encountered in ordinary practice are due to conditions which are apparently foreign to the immediate digestive function. They may and do require special methods of investigation, but when it comes to an interpretation of the results obtained, too great specialization can well obscure the issue. Here is required a far greater breadth of vision than ordinary gastrological teaching has heretofore supplied. The prevailing opinion that the ability of the gastrologist is limited to astute detection of certain local conditions is the result of the popular demand for things tangible and mechanical. The intelligent gastrologist is the one who has the broad knowledge required to properly interpret the chemical and physical data obtained by special methods, in the light of biological, physiological, and sociological acquirements.

It is becoming more and more apparent that the operation of fortuitous discovery in gastrological observation is rapidly reaching its limit, and that whatever progress is to be made in the future must be accomplished by those whose special training in physiology and biology renders them competent to proceed along strictly scientific lines. In this regard, three directions suggest themselves: The physiological chemical, the internal secretions, and the neurological. It is the latter which is of especial importance to actual practice, for it enables the clinician to place upon abnormal functional activity its proper valuation. An inclusive knowledge of the constitution and operation of the vegetative nervous system will help much in this direction. Such knowledge will act either as a stimulus or curb. It certainly will balance judgment. It will humanize the whole subject of gastrology, and emancipate it from the narrow, materialistic conceptions into which too assiduous localism has plunged it.

There is far more to the subject of gastroenterology than intense specialism is apt to admit. There is a certain restricted field of immediate structural relationship, but the vast majority of our ordinary dyspeptic diseases extend far beyond the alimentary canal. Among other things, they are intimately related to personality. In no part of the human organism do psyche and soma meet upon such common ground. This imposes upon every gastrologist a certain philosophy. A comprehensive conception of the subject cannot be acquired by use of the microscope, fathomed in the depths of a test-tube, or mastered in the constrained atmosphere of the consulting room. For this, is required a sympathetic understanding of the fads and foibles, the hopes, fears, and ambitions of men—in short, their general outlook upon life. Any assumption of artificial dignity or superiority handicaps at the start. The intelligent gastrologist should be the unprejudiced philosopher, the "synoptic man, one who sees the verities of life in their true relations, properly coördinated or subordinated, and who, in particular pursuits, however absorbing, does not ignore the unity of the whole, nor overlook the universal aspect even of the commonplaces of life." (Hibben). As some one has very properly remarked, "it is probably no accident that organs which are for the preservation of the species and the continuity of life, possess a modeling influence upon the individual bearer of life."

THE INTERNAL ASPECTS OF PROSTATIC SUPPURATION.*

A PROBLEM IN DIAGNOSIS.

BY HARLOW BROOKS, M.D.,

NEW YORK.

(From the Second Medical Division of the City Hospital.)

IT has often been said that an important part of the education of an internist lies in a wide experience in general practice and there certainly is no branch of medicine nor of science in general which is not directly useful to him who wished to qualify as a competent practitioner and especially as a diagnostician in the field of general medicine.

While this as a general statement would, I think, arouse very little adverse criticism, it is quite possible that many of us underrate the desirability of an intimate knowledge of the disorders of the genital tract as of particular moment to the internist. This is in large part due to the fact that general medical men as a rule have not thoroughly considered these problems in their systemic bearing, leaving them rather to the care of a specialist in these lines to whom quite naturally the internal aspects do not appeal.

The very direct bearing of genital disease on internal problems is well illustrated in the numerous metabolic, neurotic, and vasomotor disturbances which arise at the times of puberty or of the menopause. Chlorosis, hyperthyroidism, myxedema, dispituitarism, and many gastrointestinal disturbances, for example, are so closely interwoven with abnormal function of the genital glands that they require but illustrative mention here.

While this dependency is now more frequent and striking in female diseases than in those of the male, it is highly probable that this is largely because these problems have been studied less in men than in women.

It has fallen to my lot during the past few years to see several cases in which general symptoms of a very striking and confusing character have developed as a result of prostatic disease, and I wish to call your attention this evening to certain of the aspects of prostatic suppuration.

Naturally, suppurative prostatitis most frequently originates from a urethritis in which infection of the prostatic portion has taken place. It is therefore a frequent condition in the course of gonorrheal urethritis. It is a curious fact, generally recognized however by genitourinary specialists, that when such a prostatic infection takes place in the course of a urethritis, even when it is an actively suppurative process, there is a cessation, though perhaps very transitory, of the urethral discharge. Hence it is that cases of this manner of origin may present themselves before the internist with the urethritis no longer apparent or active. The patient may thus entirely mislead the physician as to the cause of the disturbance perhaps quite innocently, since the indications of local disturbance may have been at the worst very few.

Suppurative prostatitis may also arise as a result of direct infection from the presence of prostatic calculi, particularly such as cause a rather high grade of local irritation. It may and not infrequently does occur as a result of a proctitis and is even more common in cystitis, orchitis, or vesiculitis, either of which conditions may exist in suf-

*Read before the Bronx Medical Society, April 7, 1915.

ficient degree to cause this complication without local symptoms of sufficient moment, especially in chronic cases, to suggest clearly the point of origin.

In many instances the infection appears to be caused by a relatively innocent organism, particularly by the colon bacillus or, as I have found in several instances, by a member of the proteus group. There is considerable evidence to suggest that it may and perhaps frequently does follow hyperemia of the prostate, resulting from numerous conditions. That it may be at least invited by chronic constipation, particularly when this is associated with straining at stool or with hemorrhoids or fissures, seems highly probable. It may also develop from traumatic causes as from horseback or bicycle riding, especially if on an improperly fitted saddle. A certain number of cases develop in the course of mumps and some from metastatic foci in general infections. The common association of the condition with prostatic hypertrophy is of course obvious.

Depending somewhat on the point and type of origin the prostate becomes variously infected. The follicles alone may be involved, or the follicles and interstitium, or perhaps an isolated abscess or yet a diffuse suppurative process involving practically all parts of the gland. Though to the genitourinary surgeon, these various points of etiological and anatomical difference may be very essential, from the viewpoint of the internist it is relatively unimportant since the general aspects of the condition in either instance are practically identical.

The course of the infection may be toward either absorption or abscess formation in any instance. Where abscesses are formed they commonly sooner or later rupture either into the urethra or into the periprostatic tissues. When rupture into the urethra occurs, the condition commonly declares itself in a very evident way by the discharge of pus into the urethra and if it be of gonorrheal origin the urethra commonly responds by a recurrent attack of urethritis. When the abscess points into the periprostatic tissues its presence may be for a long time unsuspected or indeed may be diagnosticated only when it finally presents as a probable fistula *in ano*. Several such instances have given pictures suggesting coccygia, sciatica, or sacroiliac arthritis. Again these conditions are surgical propositions with which the internist has little to do aside from the question of diagnosis.

Before taking up what is to us this evening the most important side of the question, that is the symptomology, it may be well to point out certain anatomical and physiological characteristics of the prostate gland which render suppurative disease of it particularly suggestive.

Its intimate relation to the urethra is one of its chief anatomical points and accounts for the origin of most of the instances of suppurative prostatitis, since the larger number of infections originate from this tube. The prostate is made up of large acinous sacculations which through their ducts lead directly from the urethra to the deepest portions of the gland. It is almost impossible for an infection of the prostatic urethra to exist without more or less prostatitis. These acini are supported by an interstitium into the structure of which many smooth muscle fibers enter, and in the course of the physiological activity of the gland the contraction of these fibers compress the acini, driving their secretion out through the ducts into the urethra. The very dense fibrous capsule which limits the prostate externally is the reason that many extensive suppurative processes are strictly limited to the gland and also explains why most suppurations eventually rupture internally into the urethra instead of into the soft tissues surrounding the gland.

As to the physiology of the prostate, little in detail may be considered here except to point out that it is an active gland, the secretion of which is of very great importance in relation to the sexual functions. Reasoning from analogy as well as from clinical and experimental observations, it seems highly probable that the gland has also an important internal secretion which plays a very definite rôle in the general condition of the body, perhaps in the formation of hormones which may profoundly influence the psychic as well as the more purely physical functions. Its analogue in the female is the uterus, and the prostate is graphically and correctly called the uterus masculinus. This hidden function may well explain why even small and relatively insignificant disease processes of this gland may profoundly influence the whole body.

The definite symptoms which result from prostatic suppuration may be conveniently discussed under the heading of *local* and *general*. The former are of importance from our viewpoint only in that they materially assist in diagnosis and largely determine treatment. The general symptoms on the contrary are those of greatest bearing on the problem which we have set for ourselves this evening.

Where the infection extends in from the urethra, we have already mentioned the almost regularity with which urethral discharge, if any be present, ceases, at least temporarily. Pain is present in a very high percentage of cases, but it may be entirely absent or unnoticed in instances in which the infecting organisms are of very low grade of virulence, where the suppuration has been of very slow evolution, or where the involved focus is small. Suppuration of considerable severity may be frequently unnoticed, apparently due to a relatively low grade of sensitiveness of the organ, notwithstanding the fact that it is so firmly and rigidly limited by its dense capsule which in ordinary conditions would make inflammatory processes particularly painful. Tenderness is much more marked and constant than pain and in not infrequent cases as one sees it on internal services, no pain may be complained of and yet when rectal examinations are made or during defecation a considerable degree of tenderness may appear. Sometimes a certain amount of obstruction to the urinary stream exists, depending, of course, on the degree of tumor caused by the inflammation or the edema consequent upon it. In such circumstances, tenesmus, ardor urinæ, and a reflex constipation may be present. Swelling and actual prostatic tumor usually accompany such symptoms. Doubtless the most impressive and striking general manifestation of prostatitis of the suppurative type is prostration. Many genitourinary surgeons in their descriptions of the general manifestations of this condition describe them briefly as typhoid. By this term is included with the general picture of prostration, coated and tremulous tongue, fetid breath, sordes on the teeth, herpes about the lips, and abdominal inflation, commonly with constipation but occasionally with diarrhea. A degree of mental depression which in some cases amounts to somnolence approaching coma, indifference to surroundings and great physical as well as mental weakness, are very generally seen.

Temperature elevation is almost invariably present and when the case falls under observation early in the course of the disease the temperature is found to mount slowly, corresponding more or less certainly in degree with the grade of prostration. The morning remission customarily observed in ordinary suppurative processes does not appear in this disease but the temperature course preserves a steadily ascending character or remains fairly constant at a level which may be high or low. Temperature does not correspond very definitely with the degree of prostration which then seems to be an independent symptom. Even in cases where slight variations only appear in the temperature level, slight rigors are likely to develop, sometimes actual chills, not infrequently with no variation in temperature.

Profuse and drenching perspirations are very frequently present, followed of course by a period of accentuated exhaustion but often also without effect on temperature.

The pulse rate also presents a curious anomaly further simulating the picture of a true enteric fever. Proportionate to the temperature the pulse rate is low, though it varies following gradually the temperature curve. I have never observed dicrotism in suppurative prostatis, but the pulse is customarily full, easily compressible, and with a slow rise and rather deliberate fall. The blood pressure in the cases that I have studied as to this condition is either normal or subnormal. Later in the course of the condition the temperature chart may take on the aspects of a typical sepsis, with the characteristic morning rise and evening fall. As a rule, however, by this time the definite local signs of abscess formation are present so that this sign commonly appears too late to be of real aid in the early diagnosis of the condition. With discharge of the pus, either automatically through the urethra or elsewhere or from operative interference, a prompt fall in the temperature takes place and at the same time the evidences of toxemia diminish or entirely disappear.

The blood picture is further confusing. In every case that I have examined as to this feature there has been either a normal total or a hypoleucocyte count. The differential count instead of showing a relative polynuclear increase generally shows a relative increase in the mononuclear elements, especially of the large lymphocytes. Blood cultures in all the instances which I have studied have been negative.

Throughout the entire course of the process until the pus finds escape, the chief clinical characteristic of the disease is the prostration which in many if not most instances exactly approximates that of a true typhoid fever. A very astonishing feature of the disease may be the lack of localizing symptoms. In several instances no local complaints whatever have been made by the patient and the condition has been discovered only when pus appeared in the urine, when a perineal abscess pointed, or when as a matter of clinical routine a rectal examination disclosed the origin of the disease picture. Inquiry among my friends has convinced me that I have not been by any means the only clinician who has frequently mistaken the condition for a typical typhoid or paratyphoid fever.

The chief points in early differential diagnosis are mostly those of laboratory detail. The Widal reaction is, of course, always absent, though, as in most febrile conditions, it may be simulated at times. Blood and urine cultures are negative as to typhoid and paratyphoid bacilli. It is highly probable that the urine cultures may in some cases show the presence of other organisms, such as the colon bacillus or proteus bacillus, which I have found on a few occasions, or of the gonococcus or other pyogenic organisms. These, however, I have never looked for until pus appeared in the urine and when found, if their real condition is unsuspected, their presence is usually accounted for as a technical or laboratory contamination.

With all absolute laboratory tests constantly negative, of course one sooner or later excludes typhoid fever, but for a long time thereafter the possibility of a paratyphoid infection exists and the diagnosis of a miliary tuberculosis of the typhoid type comes to be seriously considered. The exclusion of this possibility also depends upon laboratory tests, though, of course, when the case has been studied for several weeks the lack of rapid progression and the non-appearance of typical signs of this condition also tend to exclude this. In this regard I believe that lumbar puncture, with the thorough centrifugation of the cerebrospinal fluid and examination for tubercle bacilli, is very helpful.

Of course, the final and absolutely diagnostic feature of the syndrome is the examination of the prostate per rectum, and the consequent discovery of an abscess or of a prostatitis. In all the cases which I have seen diagnosis has been easy once that rectal examination has been made. The treatment of the condition is, of course, surgical and because of this I am not competent to discuss it. Where operation is refused or deemed unwise I wish to suggest the possibility of successful vaccine treatment.

W. M.—A previously healthy physician, 24 years of age and an interne on the medical service of a large general hospital, noticed that for some two weeks he had been unable to carry on his work in a satisfactory way. He was inordinately tired at night, depressed, had loss of appetite and marked malaise. He was found to be running a night temperature gradually ascending day after day until when seen a night temperature of 103° was recorded. The pulse had been relatively low and the respiration rate throughout remained normal.

Physical examination revealed a practically negative condition, especial attention being devoted to the pulmonary status, notwithstanding the fact that no cough was present. Blood examination showed on this as on frequent other occasions a somewhat lowered hemoglobin percentage, but a normal red cell count and a total leucocyte count varying between 3,500 and 5,000. The differential counts showed a relatively high percentage of lymphocytes and mononuclears with relatively low polynuclears. Blood cultures were always negative.

For three weeks the temperature remained practically constant in the region of 103°. Prostration was extreme and profuse sweats were present. At times a mild delirium was manifested. Numerous Widal tests were made, always with negative results, and the urine and feces were cultured for typhoid and paratyphoid organisms also with negative results. At times the urine contained leucocytes in more than usual numbers but aside from probable external infections it remained sterile.

No pain was complained of at any time except for persistent and very severe headache, and though the patient was seen by many members of the house and visiting staffs, no absolute diagnosis was made. Cultures of the cerebrospinal fluid tended to negative the probability of a miliary tuberculosis and the general consensus of opinion was that the case was a severe type of partyphoid fever, though neither cultural nor serum tests confirmed this hypothesis. Meanwhile the prostration remained very grave and the patient had emaciated rapidly. Finally the patient remarked that

occasionally on defecation or when taking an enema some rectal discomfort was present. Rectal examination some four weeks after onset showed the presence of a small prostatic abscess which shortly ruptured into the urethra after which prompt fall in temperature and rapid and complete convalescence took place.

Cultures showed the abscess to contain colon bacilli and mixed staphylococci. There was no history of a previous gonorrhea or urethritis of any kind and the origin of the abscess is unknown.

In conclusion I wish to call to your attention the fact that this condition may exist without localizing symptoms of definite character and that it will induce a clinical picture almost identical with that of typhoid except as to bacterial findings. It is extremely common and it is readily diagnosticated when one considers the possibility of its existence.

44 West Ninth Street.

ON THE NATURE OF THE NEUROSES.*

A CONTRIBUTION TO THE STUDY OF THE NEUROTIC PERSONALITY.

By LOUIS CASAMAJOR, M.A., M.D.,

NEW YORK.

CHIEF OF CLINIC, NEUROLOGICAL DEPARTMENT, VANDERBILT CLINIC; INSTRUCTOR IN NEUROLOGY, COLUMBIA UNIVERSITY; ASSISTANT NEUROLOGIST, CITY HOSPITAL.

To the mind of every physician working in the clinics of every large city must frequently come up the question, "Why is a neurotic?" Day after day we see come and go in our dispensaries what seems to us a never-ending line of unfortunates, full of complaints verbosely described, which on examination reveal little of physical signs for substantiation. The type is so well known in all clinics—for the neurotic is a confirmed explorer into all fields of medical aid—that often he is dismissed with but superficial investigation, with a wave of the hand and a bottle of rhubarb and soda, classified as a "neurasthenic," generally with a profane prefix. Of course the neurological clinics secure the most of these cases, for sooner or later the neurotic comes to regard his trouble as "nervous," and seeks aid in the neurological clinic, where indeed he too seldom finds it.

In spite of the multiplicity of symptoms the type is not difficult of recognition. Although the diagnosis is often made falsely and an individual with a serious organic disease, not always of a rare or unusual nature, wanders around the clinics undiagnosed for months or years; nevertheless, in my opinion, this mistake is not often made, and in the large majority of cases the diagnosis stands. We all recognize the neurotic, often as soon as we see him, yet we are very much at a loss when we try to explain on what grounds our opinion is formed, which loss we express clearly in the time-worn remark, "This impresses me as a functional condition." It is the purpose of this paper to attempt to point out in very sketchy fashion some of the fundamental and characteristic points which neurotics have in common.

About one case in every four or five in our neurological clinics can be diagnosed as functional. Some among these easily fall into fairly well defined groups, as hysteria, primary neurasthenia in Freud's sense, anxiety neurosis, and compulsion neurosis; but in among these and all around them is a much larger group of undifferentiated, unclassified clinical pictures of ever varying nature, labeled psychasthenia, undifferentiated neurosis, simple neurosis, neurasthenia, or just plain nervous. It is especially this latter group which the writer wishes to consider here.

Among these patients women are found in somewhat greater numbers than men. The great majority are foreign born, but this is little surprising in a city where the preponderance of the population is not native. There can be no doubt that most of the neurotics of our clinics are Hebrews, mainly those coming from Russia and the Polish states. Among them one seldom sees the very young or the very old; almost all are in the active years of life when competition and the necessity of earning a living for themselves and usually for others should occupy their thoughts and interests.

The most frequent symptom complained of is pain, and it is very exceptional to see a neurotic who is unable to find at least one pain to dress up and parade before the physician. Among the Hebrews there exists a wonderfully extensive vocabulary of pain. While most of us are satisfied to describe our pains as "sharp" or "dull," these people possess a wide range of expression. Simple, "schmerzen" seems to differ from "drehen," which again is distinguishable from "stecken," "ziehen," "brechen," and more, each of which appears to have its own tone value. This tendency to catalogue pains so characteristic of the neurotic is always an important point in the diagnosis.

The location of these pains is very varied, but most often they are in the legs, the head, and the heart; important members and organs for the active life of the individual. The detailed way the neurotic speaks of his pains, the amount of affect he displays and the obvious desire to impress the physician with the great seriousness of it all show too clearly how much thought and reflection he has given to the development of his clinical picture. The more intelligent the patient and the greater his field of experience, the more complicated is the disease picture he paints. Among the ignorant the symptom expression is mainly in the field of somatic sensation—muscle weakness, paresthesia, and particularly pain, that great indicator of diseased function. Only the ignorant are capable of holding on to their pains which molest them for years, without interfering with their bodily weight, their sleep, and a reasonable enjoyment of life. The more critical easily perceive the inconsistencies of these clinical pictures and hence must take refuge for their symptom expression in other levels of nervous life: the psychic, on one hand, in the peculiar dizziness, the thought troubles, the fears, etc., or the vegetative, on the other hand, in the glandular and organic complaints.

This brings us to the first element in the nature of the neuroses. The neurosis is an explanation. It requires but little conversation with the neurotic for one to realize that he has devoted considerable time and thought and interest to the development of his picture and the cataloging of its symptoms. Most often they come to the physician with the diagnosis ready at hand and ask for treatment for "rheumatism," "neuritis," "paralysis," or what not. The older the neurosis, the more elaborate the symptom complex presented, for the neurotic enjoys talking over his troubles with any who will listen, swapping symptoms with others of his kind, acquiring here a new symptom, there a new explanatory term, the more firmly to establish a foundation for his personal philosophy.

*Read before Staff Conference, Bloomingdale Hospital, White Plains, N. Y., Feb. 17, 1915.

Much of the psychic energy then of the neurotic is devoted to attempts to find an explanation for his condition. That he feels badly is obvious and real, and the neurosis is the attempted explanation of why he feels badly. Hence the multiplicity of symptoms, the careful classification of feelings, pains, and other symptoms, and the utilization of diagnostic and explanatory terms in portraying them; for each neurotic must build his neurosis according to his needs and his ability. Probably the most characteristic point in the neurotic's tale is his extremely loose use of terms, and his devotion to terms of loose meaning. "Rheumatism" is ever a favorite—that term of pseudo-diagnosis, which has been spread, in popular and indeed in medical use, in such a thin layer to cover so large a number of conditions, that it has ceased longer to have a diagnostic significance, and conveys now no more real meaning than does the original word "pain" for which it is substituted. The same may be said of "neuritis," merely another way of saying pain—an explanation which explains nothing, and when combined with the foregoing in "rheumatic neuritis" we have a term of sufficient inaccuracy to satisfy the most fastidious neurotic. And then there is "nervousness," a massive, elastic blanket, which can be stretched to cover the whole field of chronic human disorders, from flat feet to the character changes of dementia precox. One could add to the list "uric acid in the system," "hardening of the arteries," "weakness of the blood," and hereditary tendencies, sonorously called "diatheses"—all pseudo-explanations, substitutions of words for ideas, until we see what is so characteristic of the neurotic, a veritable fetish of words.

The neurotic culls his explanatory terms from whatever source he can, the conversation of others, the newspapers, patent medicine advertisements, and, all too frequently, the physician. He is seldom satisfied with the explanations he elaborates, and he ever seeks new fields, not only in medicine and quackery, but in other forms of healing in all levels from the mechanical to the religious. When he finds a philosophy which completely fills his needs in accordance with his ability, especially if he is able to substitute devotion to an idea for devotion to symptoms, there he finds a cure and reverts to a blissful state of self-satisfaction, which is health for him. And so the neurosis is an explanation, which does not explain satisfactorily. The neurotic means something, but the neurosis is not what he means.

This brings us to the second element of the neuroses. The neurosis is a substitute. It is because it is a substitute for something else that it is not satisfactory. When one listens to the verbose recitals of the neurotic it is very evident that he is endeavoring to explain something. A little critical study of the neurotic's talk quickly reveals the fact that it is a wealth of details with no point, and the adage that "language is a means of disguising thought" is never more truthfully applied than to the neurotic. He thinks and talks freely on every phase of his difficulty, except the point, for if he should get the point, he would cease to be a neurotic. Possibly he might be something worse. Time does not permit me to go deeper into this phase of the subject, for it leads into the realm of psychic repression, a monstrous well, which apparently has no bottom. Suffice it to say that the psychic causes are entirely egocentric, having to do mainly with the conflict between ideals and ambitions, on one hand, and instinctive tendencies and methods of life, on the other. The frequency with which one hears of the diagnosis of "sexual neurasthenia" or "sexual neurosis" speaks eloquently for the participation of one great instinct in the etiology. The neurotic is essentially an idealist, an idealist who has hitched to a lofty star his wagon, frequently improperly equipped to travel on the earth. One cannot help but reflect on the causative value of this conflict between the ideal and the real, when one recalls how seldom, if ever, one sees neuroses among prostitutes, except those who have undergone a reformation.

There is but one other element of the neuroses I would speak of here. The neurosis is an asset. Every neurotic has something to gain by being a neurotic, and he ceases to be so when this element of gain disappears. This may be otherwise expressed: that the neurosis clothes a wish. Bailey in his article "The Traumatic Neurosis" has brought this point clearly in the foreground. The wish element in hysteria is too well known to call for corroboration, and how superficial that wish may be is shown by Ames in his cases of psychic blindness. In many of our traumatic neuroses the asset value of the neurosis may be measured in terms of monetary currency in the hope of a favorable verdict from the jury, which latter usually effects a cure. This exemplifies the statement made above that the neurosis ceases to exist when it ceases to be an asset. In the occupation neurosis with the spasm and pain symptoms, this asset element is little less clear, for at least it gives the individual an easy excuse for relinquishing a remunerative position, which is unpleasant, especially in an individual who has not the mental bravery to settle otherwise the difficulties which beset him.

In many of our neuroses the asset element is not so clear, but nevertheless it is present. At best it gives the individual an excuse for leading a more or less easy life, surrounded by the sympathy which civilized people feel is due the sick. Again, it occupies so much of the patient's mental life that there is little left over for other things, especially insight. David Harum's remark that "a reasonable amount of fleas is good for a dog, as it keeps him from brooding over being a dog" might be paraphrased for the neurotic, "A reasonable amount of symptoms is good for the neurotic, as it keeps him from reflecting on his being a number of other things at variance with his ideals, and much less pleasant."

40 East Forty-first Street.

STAPHYLOCOCCUS SEPTICEMIA COMPLICATED BY SUBPECTORAL ABSCESS.

By G. A. RUECK, M.D.,

NEW YORK.

This case is reported on account of the gravity of infection, the favorable result obtained, and the fact that it is a rare condition. Von Bergmann and Mikulicz state in their "Surgery" that all the cases of subpectoral phlegmon having come to their knowledge were due to ordinary streptococci with two exceptions, one being due to *Streptococcus mucosus* and the other to *Streptococcus pneumoniæ*. Kümmel found among 1,080 cases of phlegmon treated during one decade at the hospital in Eppendorf only 26 cases of phlegmon of the thoracic wall. (Handbuch der Praktischen Chirurgie, Von Bruns, Garré und Küttner, Vol. II, p. 711. Stuttgart, 1913.)

There is nothing in the family history which is of any importance in regard to the present illness.

Previous History: The patient, Maurice D., born in U. S., 25 years old, single, a senior student of dentistry, had measles, whooping cough, chickenpox, and scarlatina when a child, diphtheria at 15, pneumonia at 17, and bronchitis at 23. He has been fairly active in athletics and is a good walker, swimmer, rower, tennis- and baseball-player, and an artist on the violin.

Habits: He uses alcohol very moderately, drinks one cup of coffee or tea, and smokes two packages of cigarettes a day.

Venereal history: He had a gonorrheal urethritis of 8 months standing at the age of 22 which resulted in a stricture at the peno-scrotal junction. Sounds were passed six times in order to dilate the stricture. At the age of 24 he had a second gonorrheal infection of the urethra. The discharge lasted 7 months, the stricture closed up, and the prostate became inflamed. Sounds were passed but no operation upon the prostate was performed. In January, 1912, he was operated upon for an ischiorectal abscess. The wound discharged for 9 months. A fistula formed which was excised in September, 1912. Then the wound healed in 1½ months.

In January, 1913, he suffered with furunculosis of the neck. Appetite, bowels, and sleep were normal before the present illness. Urination: Three to four times a day; the stream is small, twisted, and spattered. At times, especially after erection, the patient notices a "soreness" in the urethra. It takes him a considerable time to empty the bladder. For the last three months the patient has been very active socially and has been studying hard for his examinations, being therefore "physically run down."

Status præsens: He was taken ill February 26, 1913, with pain in all the muscles of the left shoulder and with fever. He received a vigorous antirheumatic treatment with aspirin by Dr. J. McP. who kindly transferred him to me, March 6, 1913, with the diagnosis of "acute muscular rheumatism involving the muscles of the left shoulder, due to autointoxication." I first saw the patient March 6, 1913, late at night. He was feverish, his tongue was coated, and the breath offensive. The muscles of the left shoulder were painful, and the left arm could not be raised. There was no visible swelling. Examination of the heart, lungs, and abdomen gave negative results. Suspecting gonorrheal myositis, I injected into the patient's arm one dose (2,000 million) of a polyvalent gonorrheal vaccine which I happened to have in my handbag. I discontinued the antirheumatic medication and ordered instead two rectal irrigations a day with one quart of physiological saline solution, one hot bath a day for 20 to 30 minutes, and a high caloried liquid and soft diet. (Two rectal saline irrigations were given twice a day for one week, then once a day until the patient got up. The hot baths were taken for one week only.) That night the patient suffered with insomnia. Next morning he had headache, "a bad taste" in the mouth, and pain in the left arm and upper part of the left side of the chest. I made several blood-cultures and took enough blood for agglutination and complement fixation tests. The agglutination and complement fixation tests for gonorrhea were negative. March 8, I obtained a growth of a staphylococcus in the blood cultures, and the following day I made an autogenous vaccine from transfers on meat infusion and ascitic agar. My diagnosis of the case was now "Staphylococcus septicimia plus acute inflammation of all the muscles of the left shoulder joint due to the staphylococcus present in the blood."

March 10. The first dose of 500 million dead bacteria of the autogenous vaccine was given into the patient's right arm. The left arm was painful especially in the arm pit. The axillary glands were slightly swollen. The chest "felt tight" and the patient "hardly dared to breathe."

March 11. The patient slept well all night. In the morning he could raise the left arm slightly; but he had headache and anorexia. I obtained a catheterized specimen of urine from which I made cultures. These yielded the same organism as the one obtained from the blood.

The urine was amber colored, slightly turbid, small flakes, after standing clear, with light mucous sediment; specific gravity 1026, acidity 130 (in terms of $\frac{n}{10}$ sodium hydroxide), faint trace of albumin, trace of bile, no sugar, slight increase of indican, no casts, no crystals, epithelial cells rare, a few Gram positive micrococci.

Smears from the tongue and pharynx showed staphylococci in great numbers and only a few other bacteria.

March 12. The left arm is very painful. There is a slight swelling of the left shoulder. The axillary glands are slightly enlarged. The external portion of the left pectoral muscles is painful. The pharynx and posterior faucial pillars are red, the tongue is coated, the throat and mouth feel dry, the back of the throat feels sore. A second dose of the vaccine, 1000 million bacteria, was given into the right arm.

March 13. The condition of the patient is the same as the day before. The patient received ¼ gr. of morphine every 4 hours when in pain. Upon the wish of his friend, a recently graduated doctor, I injected twice hypodermically 20 c.c. of the Hiss leucocytic extract, but without apparent effect.

March 14. The arm pit is slightly swollen but there is no fluctuation in the axilla nor bulging of the left pectoral muscles. He complains of pain in the left side of the pelvis.

March 15. The patient looked very ill. Under a general ether anesthesia I made an incision 2 inches long at the most dependent portion of the left axilla close to the outer border of the pectoralis major. About one pint of pus escaped from the wound. A sponge holder introduced into the wound could be passed to the clavicle, the left border of the sternum, the axilla, and under the scapula. The wound was drained by a rubber tube for 5 days and was dressed once or twice a day for 11 days, then once every second day until May 9, 1913. The discharge was a malodorous pus containing the same organism which was found in the blood. The muscles of the entire left shoulder girdle were massaged lightly and cautiously every day, the movements of the massaging hands being directed toward the wound. There was pus beneath the scapula and in the shoulder joint, the latter draining without surgical interference into the axilla. Adhesions in the shoulder joint were prevented by a single passive motion of the arm in every normal direction whenever the wound was dressed.

March 24. There is an increase of temperature and, for the last 4 days, great tenderness in the left side over the lumbosacral junction of the spine.

March 25. Under local novocaine anesthesia I made an incision down to the left side of the last lumbar and first sacral vertebræ. No pus was found. The wound was sutured and not drained. The axillary wound was discharging a little, the gauze being only slightly wet.

March 29. There is a moderately profuse discharge from the axilla. The patient looks bright and has a good appetite.

April 20. The patient has been out in the fresh air every day for a week. The arm is still painful. The discharge is slight, consisting of serum and blood. The patient received in all 8 doses of the autogenous vaccine.

The patient was perfectly restored to health. He can move his arm and shoulder freely in all normal directions without pain.

We have here a case of a general septicemia due to a *Staphylococcus pyogenes* infection complicated by a subpectoral abscess, the latter extending into the axilla, beneath the scapula, and into the shoulder joint. It was a general infection from the beginning. The infection started, according to my opinion, in the mouth, as no wound or abrasion of the skin of the entire left arm or an inflammation of the axillary lymph glands or any small wound in other parts of the body was noticed before the illness began and as the smears from the mouth showed numerous staphylococci and only a few other bacteria.

This staphylococcus resembled *Staphylococcus salivarius pyogenes*. The serum of a rabbit immunized with it agglutinated suspensions of *M. salivarius pyogenes*, *Diplococcus crassus*, *M. aureus pyogenes*, and *M. albus pyogenes*, which are all, according to newer investigations, strains of the same organism. It was agglutinated by the serum of the patient.

The good result in this case is very gratifying,

(1) as joints are usually crippled by a suppurative process due to a staphylococcus infection; (2) as a septicemia complicated by a subpectoral abscess is, according to von Bergmann and Mikulicz, a condition which is often very difficult to diagnose and which is almost always fatal.

The case teaches that 1. In "acute rheumatism" we have to look out for blood infections and make blood cultures; 2. A subpectoral abscess should be drained as early as possible; 3. A single incision in the most dependent part of the axilla may drain a subpectoral abscess and it is not necessary to make several and very large incisions as recommended by prominent authors; 4. An autogenous vaccine, if possible, to be obtained early, will help to bring about a favorable result; 5. Stock vaccines should not be used unless the exact nature of an infection has been determined by proper bacteriological and serological examinations.

633 East 241st Street.

SOME DIFFICULTIES IN THE DIAGNOSIS OF GENERAL PARALYSIS OF THE INSANE.

By W. F. RICE, M.D.,

WASHINGTON, D. C.

JUNIOR ASSISTANT PHYSICIAN, GOVERNMENT HOSPITAL FOR THE INSANE.

When we consider the manifold physiological function of the area involved and the diffuse nature and varied intensity of the pathological processes found in this disease, we cease to wonder at the variety of disease pictures presented and the difficulty in the early diagnosis of all cases. Kraepelin, in his excellent treatise on "General Paresis" has distinguished the following principal forms, viz., the demented, the depression, the expansive, and the agitated, and in his discussion of the symptomatology under each of the groups, he seems to have well covered the cases generally seen.

However, in an institution such as the Government Hospital for the Insane, where about 8 per cent. of the large number of admissions are paretics, we are occasionally confronted with a case which differs in its symptomatology or which runs an atypical course and the diagnosis of which is uncertain.

I desire to present a few cases which have come under my observation, all of which have at some time been diagnosed general paresis although later developments have led us to believe that several were cases of cerebral syphilis.

The following case is interesting owing to its long duration and the difficulty in differentiating between paresis and cerebral syphilis:

Case I. Patient, a white male, aged 28 years, on admission July 25, 1906. He occupied a responsible position, having supervision of a large number of men. Family history negative except for the fact that the patient's father had an affection resembling locomotor ataxia. The patient had typhoid at the age of 14, had gonorrhea and chancroids on numerous occasions. He contracted syphilis in July, 1901, and received treatment for some five years subsequently.

He was sent to the Philippines on duty in 1903, returning in December, 1905. While in the Islands his first symptoms became manifest. He showed a loss of memory, was lazy, and came into frequent personal difficulty with his associates. On admission to this institution the patient was somewhat emaciated, muscles flabby, appetite poor, and he suffered from frequent attacks of indigestion. He was quite indolent, preferring to lie in bed most of the time. Complained of frequent headaches and nervousness, was sexually weak but not impotent. He suffered from a mild depression, was easily excited, at times talkative and occasionally shut himself in his room. The patellar reflexes were exaggerated, pupils normal. Speech was rather drawling and monotonous with occasional elision of syllables. The patient would not read or engage in any amusements. There was a partial Babinski reflex on both sides. The general mental picture at this time somewhat resembled that of dementia praecox.

On August 2, 1906, patient suffered from his first convulsion, following which he remained in a comatose state for about a half hour. He failed rapidly both mentally and physically, became exceedingly emaciated, was clouded mentally and could not recognize his friends. He refused nourishment and had to be tube-fed. There was incontinent of urine and patient became very untidy in habits. He showed marked retardation, speech became more slurring in character, the facial muscles showing marked tremor. There were no evidences of hallucinations or delusions at this time. He was treated with mercurial inunctions and showed marked improvement during the latter months of 1906. February, 1907, the patient had another convulsion and shortly afterwards an irregularity of the pupils was first noted, the left also being larger than the right. At that time the Romberg was negative, there was some incoordination, and the tendency to somnolence became more marked, the patient spending from sixteen to eighteen hours out of the twenty-four in bed. He was disoriented and memory for recent events was poor. In May and June, 1907, the patient had several attacks of dizziness, but did not lose consciousness. In August a severe convulsion occurred. The patient was placed on treatment with atoxyl every second day. Late in September another epileptiform attack occurred, followed by a peculiar sensation and numbness of the arms. Afterward his left arm became practically useless and left leg dragged somewhat. There was a slight ptosis of right eye and a drawing of corner of mouth on right side. Pupils were sluggish in their reaction to light and he could scarcely swallow. He remained in a partially stuporous condition until July, 1908, when he showed such marked improvement that he was allowed to visit Atlantic City for several weeks, returning apparently in a much better condition, but rather tired. In September, 1908, patient suffered from a severe convulsion. He went home for a visit in September, 1908, returning to the hospital in January, 1909. While away he drank considerable whiskey and went on frequent debauches. He had about four convulsions during this time. During February, 1909, he improved, but gait was ataxic and he complained of weakness of left side of body. His salivary secretion greatly increased and the patient became more untidy in appearance. Examination of the cerebrospinal fluid made July 26, 1909, showed the following: Wassermann reaction, positive; cells per cmm., 47; differential count: lymphocytes, 83 per cent.; large mononuclears, 10 per cent.; plasma cells, 5 per cent.; polymorphonuclears, 1.5 per cent.; kornchenzellen, 0.5 per cent. The Wassermann of the blood serum was positive.

Mental examination made January 3, 1911, showed patient's memory to be fair for both remote and recent events and during that year he improved somewhat mentally and physically. In March, 1911, and again in September, 1911, the patient received 0.6 gram of salvarsan intramuscularly. During the latter part of 1911 and all of 1912 his condition showed but little change and convulsions occurred occasionally. In January, 1913, the Wassermann of the cerebrospinal fluid was negative, appearance clear, protein content not increased, cells per cmm. 2. Early in 1913 he was placed on treatment with potassium iodide in increasing dosage. In December, 1913, the patient still experienced difficulty in walking, knee jerks were exaggerated, pupils were somewhat irregular but responded to light and accommodation. Slight tendency to Romberg apparent. Appetite was good and patient slept well. December 24, 1913, he was allowed to go on a visit home, returning March 3, 1914. After this he showed a great deal of improvement, enjoyed parole of the grounds, and conducted himself well. During 1914 he received potassium iodide and mercurial inunctions. He had a convulsion in June, 1914, followed by a stupor and confusion. His physical and mental condition again improved and he spent a great deal of time playing cards with fellow patients. In March, 1915, the Wassermann of the blood serum and of the cerebrospinal fluid were both negative.

At the present time the patient shows the following

symptoms: speech rather monotonous and great difficulty is experienced in the pronunciation of the test words. Patellar reflexes are somewhat exaggerated, pupils irregular in outline and react sluggishly to light. There is still a slight weakness of the muscles of the left side and the patient limps somewhat. He is still very indolent, preferring to remain in bed until midday. Memory is very poor.

In December, 1909, the mental symptoms, speech, and laboratory findings justified a diagnosis of paresis, and the case was so diagnosed. At present, however, because of the long duration of the disease and the negative character of the cerebrospinal fluid after such slight treatment, I think we can call this a case of cerebral syphilis.

The second case, while clinically one of general paresis, must be diagnosed cerebral syphilis owing to the laboratory findings.

Case II. Colored, male, driver, aged 42 on admission, May 12, 1914. Family history negative. Early life uneventful. He has apparently been a heavy drinker. First symptoms became manifest several years ago. He was irritable, irrational, talked to imaginary persons and wandered about the streets night and day saying he wanted to kill someone. On admission to this institution he was fairly well oriented, euphoric and had grandiose ideas. Stated that he was worth several millions of dollars, was personally acquainted with the President, etc. His memory was poor and he could not name the days of the week.

Physical examination—deep reflexes generally exaggerated. Romberg showed some swaying. Pupils were irregular in outline, but reacted to light and to accommodation. His speech was quite slurring in character, with marked slurring and elision of syllables and his lips were tremulous while speaking. There was a coarse tremor of the hands and of the tongue.

Shortly after admission he became quite negativistic and refused food, saying that he was tired of living. In May, 1914, the Wassermann of the blood serum was complete positive; of the cerebrospinal fluid negative, protein content increased, cells per cmm. 12. On December 12, 1914, the Wassermann of the fluid was still negative, cells per cmm. 7. Up to the present time this patient's condition has shown very little change.

The third case is remarkable for the frequency with which it has been necessary to change the diagnosis during a period of about ten years.

Case III. White male, single, occupation driver, aged 37 on admission, December, 1905.

Family history—father suffered from melancholia and died of paralysis. One sister died of tuberculosis. Patient was somewhat addicted to the use of alcohol. Admitted excessive and unnatural sexual indulgence. Syphilis denied. In September, 1905, immediately after the death of his sister, the patient became melancholic and lost all energy. In October, 1905, he refused to work and also declined all food or drink, becoming as a result quite emaciated. He was morose and for several days prior to his admission to this institution refused to speak.

On admission he was negativistic, indifferent, somewhat catatonic and quite untidy in habits. A diagnosis of dementia præcox was made at that time.

During 1906 the patient showed marked improvement and in January, 1907, was discharged as recovered.

He was readmitted January 24, 1910. At the time of his second admission his actions and general deportment were characteristic of a high grade imbecile. Mentally he was much below par and his reactions to the various tests were very childish. He was talkative, restless and mischievous, vain and boastful. His intellectual processes were quite limited and moral laxness was evident. The physical examination was without particular interest except for a ptosis of right eye.

In August, 1910, a diagnosis of imbecility was made. In November, 1910, the Wassermann of the blood serum was negative.

During 1911 and 1912 the condition of the patient showed some improvement. His behavior was excellent. He was alert, industrious, and evidenced a fair degree of intelligence. In October, 1912, the patient became rather confused and untidy in his habits, but would have periods of remission during which he was fairly normal in appearance. In February, 1914, it was noted that the patient was disoriented, his speech was slurring in character, and test words were pronounced in a stumbling manner. His speech disorder grew worse and in January, 1915, the patient presented the characteristic symptoms of general paresis. The Wassermann of the blood serum January 3, 1915, was complete positive. The cerebrospinal fluid showed a double positive Wassermann, protein content increased, cells per cmm. 10. Accordingly a diagnosis of paresis was made.

January 15, 1915, the patient suffered from a series of convulsions, grew weaker rapidly and died. Autopsy was not obtained.

After a study of the above cases and of others observed at different times, I have reached the conclusion that we must not be too hasty in making a diagnosis of a case of syphilis of the nervous system on the clinical symptoms alone, but must depend more and more upon modern laboratory methods, which have reached such a high degree of perfection. Especially is this true when we consider the difference in the prognosis of paresis and cerebral syphilis.

AN IMPROVED AND SIMPLIFIED TECHNIQUE FOR AUTOSEROTHERAPY.

By E. E. PALMER, M.D., and WM. LEE SECOR, M.D.,

KERRVILLE HOSPITAL,

KERRVILLE-ON-THE-GUADALUPE, TEXAS.

The subject of autoserotherapy is claiming the attention of thinking physicians everywhere, as is evidenced by the number of articles and references pertaining to this subject now appearing in current medical literature. Those who have given time and study to this subject are quite enthusiastic, for most excellent results have been obtained in the treatment of some of our most obstinate diseases.

The principal objection to the method has been the difficulty in carrying out a perfect technique, outside of a properly appointed hospital.

The most common method has been to draw off a portion of the patient's blood, centrifuge it to obtain the serum, add some antiseptic to the serum and then keep it on ice for repeated use by hypodermic injection into vein or muscle. This technique, unless carried out under strict aseptic conditions, is open to considerable danger. There is too much handling of the serum.

We have been studying autoserotherapy for several years and have perfected a technique which in our hands has proven simple, logical, and effective. The results of our work have led us to believe that autoserotherapy may be made to play a most valuable part in the treatment of pellagra, pneumonia, typhoid fever, psoriasis, septic conditions; in fact, wherever a stimulation of the antigenic functions of the body is indicated, autoserotherapy is the most rational method of accomplishing it. Our technique places autoserotherapy in the hands of the general practitioner. It makes it a safe method that may be generally employed in indicated cases without fear of harm.

An area on the chest two inches square is painted with three per cent. iodine; when thoroughly dry, a piece of ordinary fly blister plaster one and one-half inches square is smeared with sterile petrolatum and applied to this area. This is protected by a cupped shield (like that used following cataract operations) held in place by strips of adhesive plaster. In about twelve hours there will be from two to three cubic centimeters of serum in the blister, and this amount has proven amply sufficient in our work. One corner of the blister is raised, and an ordinary aseptic hypodermic syringe is used to draw

out the amount of serum desired. This serum is then immediately injected subcutaneously. The plaster is carefully removed, and the blister area dressed as a burn.

The advantages that we claim for this technique are:

Simplicity—It can be used by any physician anywhere without special equipment.

Safety—The serum is not exposed to contamination and is not liable to carry live bacteria.

Efficiency—We believe that this exudate serum is more active and more efficient than the serum from centrifuged blood. The method of producing this serum would undoubtedly cause it to be richer in antigenic properties. Antiseptics are not needed. The serum changes as the disease improves, for a fresh serum is prepared for each injection.

Medicolegal Notes.

Medical Examiner's Report of Autopsy as Evidence.—Under the Massachusetts statutes providing that a medical examiner, on receiving notice that there is within his county the body of a person supposed to have come to his death by violence, shall take charge of it, and, if he thinks it necessary, make an autopsy and file with the district attorney a report of the autopsy, and that the court or trial justice shall thereupon hold an inquest, it is held that the report of the autopsy, even though a public record, is *res inter alios acta*, and not admissible in an action for death to prove the cause of death, as its statements are of matters of opinion reached by the medical examiner upon his medical knowledge, or by way of inference from answers to his inquiries, or from facts observed by himself. The examiner, however, in testifying, may use the report to refresh his memory.—Jewett v. Boston Elevated Ry. Co., Massachusetts Supreme Court, 107 N. E. 433.

Regulation of Practice of Medicine—Drugless Healing.—In proceedings in the Michigan courts for practising medicine without a license in violation of the statute, the defendant claimed that he did not make use of drugs, but practised as a "chiropractor," treating patients by manipulation of the spine and muscles of the back. The question was raised whether the title of this act, "An act to provide for the examination, regulation, and licensing of physicians and surgeons," covers and applies to the practice of medicine. The defendant contended that the act is not one for the regulation of the practice of medicine, but one for the regulation of physicians and surgeons. It was held that the act is not only one to regulate but to examine, register, and license them. The police power to license, as indicated in the title, is the recognized power to authorize persons to engage in vocations which need special surveillance, without which they could not be permitted. The words "persons practising medicine" were held to be synonymous with "physicians." The following States have held that the practice of various systems of drugless healing, the respective merits of which the courts cannot and do not assume to decide, is to be regarded as practising medicine: Alabama (osteopathy); Nebraska (osteopathy); Washington (osteopathic and magnetic); Illinois (magnetic healing in the nature of osteopathy); Iowa (neurology and ophthalmology); South Dakota (ophthalmology, or fitting eyeglasses); Iowa (vital science); Ohio (Christian Science for pay); Indiana (suggestive therapeutics); Tennessee (functional ray treatment); Indiana (magnetic healing); Texas (manipulation); Kansas (chiropractic); Iowa (chiropractic); Missouri (chiropractic); New York (mechanoneural therapy). The principles on which this line of authority reached its conclusions are comprehensively expressed in Commonwealth vs. Jewelle (199 Mass. 558, 85 N. E. 858, as follows: "It would be too narrow a view of the practice of medicine to say that it could not be engaged in in any case or class of cases otherwise than by prescribing or dealing out a substance to be used as a remedy. The science of medicine—that is, the science which relates to the prevention, cure, or alleviation of disease—covers a broad field, and is not limited to that department of knowledge which relates to the administration of medicinal substances. It includes a knowledge not only of the functions of the organs of the human body but also of the diseases to which these organs are subject, and of the laws of health and the modes of living which tend to avert or overcome disease, as well as of the specific modes of treatment that are most effective in promoting cures. It is conceivable that one may practice medicine to some extent in certain classes of cases without dealing out or prescribing drugs or other substances to be used as medicines. It is conceivable that one may do it in other ways than those practised as a part of their respective system, by either osteopathists, pharmacists, clairvoyants, or persons practising hypnotism, magnetic healing, mind cure, massage-cure science, or the cosmopathic method of healing." There are authorities to the contrary of the foregoing views, but the court concluded that the great weight of authority sustains the views above expressed.—Locke vs. Ionia Circuit Judge, Michigan Supreme Court, 151 N. W. 623.

Corporation's Liability for Medical Services Ordered by Its Agent.—In an action by a physician against a department store for professional services rendered in the treatment of one of its employees at the request of the defendant's assistant superintendent it appeared that, in case of physical injury to an employee or a customer in its store, the defendant had instructed its superintendent and assistant superintendent immediately to summon and employ a physician to attend to the injured person. The defendant claimed, however, that the authority of its superintendent and assistant superintendent in that regard was limited to the employment of a physician to render first aid to the person injured, and that they were without authority to bind the defendant for the further medical treatment of such injuries. For more than two years before rendering the services for which he sued, the plaintiff had been summoned from time to time by the assistant superintendent to attend persons who were sick or injured in the store. The superintendent and assistant superintendent testified that they told the plaintiff of the limitation on their authority to bind the defendant for the services of physicians; the plaintiff denied that he had received such information. The defendant denied liability for the plaintiff's services beyond the first treatment. As a general rule the superintendent of a mercantile corporation has not implied authority to bind the corporation to pay for the services of a physician whom the superintendent has called to attend an employee of the corporation who has been injured in the course of his employment. But the corporation, after notice of such employment, by its conduct and by its silence, may be held to have ratified the acts of its agent, or to be estopped from denying the agent's authority. And notwithstanding the absence of actual authority in the agent and the unwillingness of the law to imply such authority from the nature of the agent's general powers, nevertheless the corporation by its previous conduct, as by payment for previous like services, may have so held the agent out as one having full authority to employ physicians that it will not be permitted later to disavow the agent's acts in that regard. The evidence in the present case was held to be sufficient to justify findings that the defendant was estopped to deny its superintendent's authority to hire the plaintiff and that it had ratified the superintendent's act. The superintendent knew that the plaintiff was treating the injured employee and intending to continue such treatment as long as required, and would regard the treatment as rendered on account of the employer and to be charged to it. It was held that such notice to the superintendent being notice to the employer, in order to escape liability for such medical services, it was necessary for the employer to notify the plaintiff it would not pay for complete treatment, and that its superintendent's authority had been limited to securing first aid to the injured.—Ward vs. J. Samuels & Co., Rhode Island Supreme Court, 93 Atl. 649.

In an action for the value of services rendered it appeared that the plaintiff was called to attend an employee who had sustained a serious injury in an elevator accident. On arriving at the place of business of the employer, a corporation, and realizing the seriousness of the injury, the physician made inquiry as to who would pay for the treatment and asked that a member of the firm should be called. In response to this request the secretary in charge of the business appeared, and directed the physician to go ahead and do the best he could for the employee and take him to a hospital. This evidence was held to justify a finding of an actual contract binding the employer to pay for medical treatment rendered by the physician.—Greensfelder vs. Witte Hardware Co. (Mo.), 175 S. W. 275.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery

New York, July 17, 1915.

AN ALLEGED FALLACY OF THE ABDERHALDEN REACTION.

SOME discussion is said to have been aroused in scientific circles in Japan by the recent researches of M. Kiutsi, director of the gynecological department of the City Hospital of Hakodate, who has published his results for the benefit of English readers in a pamphlet entitled "A Contradictory Contribution Against Abderhalden's Theory of Protective Ferment." The author states that he and Abderhalden were the first to employ the term "Schutzfermente" or "Abwehrfermente" but that his later investigations have completely disproved the original hypothesis. He now proposes a new term, "Destructive ferment," "Minusferment," or "Abbauferment," which serves to break down and destroy the cells and cell substances. This ferment has a very strong resisting power, losing its activity only when heated to 120° C. for thirty minutes, and not being influenced by exposure to sunlight, *x*-rays, acids, alkalies, or the action of other ferments.

According to the Abderhalden theory the injection into the body of a substance foreign to the blood excites the production of the so-called protective ferment. Kiutsi injected into rabbits a 5 per cent. emulsion of fresh placental tissue that had been freed from blood. The urine of the rabbits was then tested daily for seven days by the author's so-called filtration process, as the result of which it was shown that the rabbit excreted the protective ferment within twenty-four hours after the injection of the placental extract. On the other hand if the latter was heated to 120° C. for thirty minutes previous to injection the protective ferment did not appear in the urine. The same results were obtained with the use of fresh sarcoma extract.

Kiutsi concludes that the protective ferment is, in all probability, present in the injected unheated material and thereby appears in the urine that is tested. Examination of fresh sarcoma tissue with the aid of the filtration process showed the presence of this ferment, which is supposed to be present in all tissues. If the ferment is isolated from the urine of a pregnant woman and is injected into a rabbit it subsequently appears in the urine of the latter. The above facts, if substantiated, would appear to demolish the very foundations of the Abderhalden theory. Instead of the living body creating the protective ferment to guard against the foreign proteins or their derivatives, this ferment is really introduced into the body with the injected material.

The presence of the destructive ferment is accounted for on the hypothesis that in all living cells there are two ferments: a constructive one—"Plusferment," or "Aufbauferment," which has the function of assimilating or synthesizing the cell substances, and a destructive ferment—"Minusferment," or "Abbauferment," which has the function of tearing down the effete cell substances and preparing them for excretion. In conditions of health there is a perfect equilibrium of both ferments. Disease may cause a disappearance of the constructive ferment with the result that the destructive ferment breaks down the cells and tissues that harbor it and then appears in the blood in which it may be detected. A marked contrast between the two kinds of ferments exists in the fact that the constructive ferment is very unstable, demanding for its existence a great many conditions, whereas the destructive ferment is highly stable, resisting a temperature even of 110° C.

THE CONTINUING MENACE OF TETANUS IN THE WAR ZONE.

Drs. Gudgeon, Gardner, and Bawtree have been investigating the bacterial flora of wounds produced during the present war and have published some of their findings in the *Lancet*, June 12, 1915. With regard to the occurrence of *B. tetani* they state of the eleven patients in whose wounds the bacillus of tetanus was found nine had been treated prophylactically with tetanus antitoxin at an early date and at no time did any one of these exhibit any symptoms of tetanus.

It is pointed out that it is of considerable importance to realize that a wounded man may be acting as a carrier of the bacilli of tetanus for at least two months after the date of the wound, and probably for a much longer period, without any reason or chemical grounds to suggest that these bacteria are present in the tissues. Whatever the nature of the wound, whether it be slight or severe, without a careful bacteriological examination it is impossible to be sure there are no tetanic spores lurking in its depths. The extreme difficulty of killing these pathogenic anaerobes makes it incumbent upon those called upon to treat wounds incurred in the war, and especially in Northern France and Belgium, to take very special precautions to prevent their spread as well as to cure those infected. In the first instance, great care should be taken to sterilize effectively surgical instruments which have been used in operating upon wounds. If this be not done tetanus is certain to be communicated. Prophylactic injections of antitoxin, as previously noted, have been proved to be of the greatest service and the writers of the paper state that such injections, when promptly given, have been the means of saving the majority of patients seen by them from this most serious disease arising from wound infection.

THE CLINICAL STUDY OF BLOOD-SUGAR.

Although clinicians have for a long time recognized the possible clinical importance of a determination of the sugar content of the blood, the routine use of this procedure has been neglected on account of the difficulty of the technique and the large amount of blood required. The improved method devised by Kowarsky about two years ago has apparently overcome these handicaps. With a modification of its technique, the simplicity and accuracy of the Kowarsky method have appealed to S. Strouse, assisted by I. F. Stein and H. Wisely (*Bulletin of the Johns Hopkins Hospital*, June, 1915), who with its aid have made an important clinical study of the sugar content of the blood.

The necessity of determining the variations in the blood-sugar is illustrated by a case of obstinate furunculosis in a young man in whom, although examination of the urine did not reveal the presence of any sugar, nevertheless examination of the blood showed a definite alimentary hyperglycemia. This examination was indicated particularly in view of a distinct diabetic family history. In this patient a strict carbohydrate-free diet resulted in a prompt healing of the lesions and the prevention of new ones. This case teaches an important lesson: hyperglycemia may exist without glycosuria. It also suggests two promising lines of investigation, namely, the early changes in diabetes mellitus and the interrelations between glycemia and glycosuria.

The authors conclude from a study of 61 determinations that the normal blood-sugar varies from 0.04 per cent. to 0.12 per cent. with an average of 0.84 per cent. These variations are attributed to the varying factors in the ordinary day of the normal individual, especially to the diet factor. Of course, an increase in the carbohydrate intake raises the blood-sugar. In the normal man this describes a curve which reaches its lowest limits before breakfast and before dinner and invariably shows a rise one hour after meals. To be of any value blood-sugar determinations must be performed before and after an ordinary meal containing carbohydrate.

A Laryngotracheal Sign in Pleural Effusion.

This sign is described by Luciano Meoni in the *Rivista Critica di Clinica Medica*, June 5, 1915. Its virtues consist in its simplicity and in its constancy as a diagnostic index. In cases of unilateral pleural effusion in a thorax of normal conformation, and not accompanied by any pulmonary lesions, there is a deviation of the trachea toward the side of the effusion. This deviation is rendered visible in the following manner: A thin strip of paraffin is fastened to the midline of the neck in front from the cricoid cartilage down to the episternal notch. By careful inspection one may observe the lateral movements of this strip which are exactly those of the trachea during the act of respiration. The deviation occurs during inspiration and is more pronounced at the lower end of the paraffin strip. In cases of bilateral effusion the deviation is toward the side of the greater effusion. It is questionable whether this sign will supplant any of the well-established methods of detecting pleural effusion. Nevertheless, the laryngotracheal sign may be of eminent confirmatory value in cases in which the ordinary physical signs are not conclusive. Possibly future studies may reveal an extended field of usefulness of this phenomenon in the study of the lateral movements of the visible portion of the trachea, particularly in cases of unilateral lesions of the lungs.

The Lactose Treatment of Diabetes.

For a long time it has been known that the administration of lactose in some cases of diabetes is followed by a marked diminution or even a disappearance of the glycosuria. Fernand Farges (*Gazette Hebdomadaire des Sciences Médicales de Bordeaux*, June 6, 1915), reports the excellent results he has obtained with this method in a series of seven cases of diabetes. In some of the patients the diet was restricted to two quarts of milk daily with the addition of from 20 to 30 grams of lactose, and in other cases the patient continued his regular diet to which the lactose was added. In most of the cases the sugar disappeared completely from the urine. In other instances the glycosuria was considerably diminished. The author concludes from his experience that lactose is completely assimilated by the diabetic. At the same time it appears to augment the assimilation of other carbohydrates that are ingested with it. Lactose is ordinarily a diuretic but in the diabetic it has the opposite effect. As a supplementary article in the diet of typhoid fever and other diseases requiring an easily assimilated nutrient, milk sugar plays an important rôle. In diabetes its rôle is a double one: First, as a nutrient, and second, as an agent that greatly increases the carbohydrate tolerance of the individual.

Exhaustion as Distinguished from Fatigue.

The nature of exhaustion is far from being understood. It differs from mere fatigue in that something in the body is actually used up and cannot be made good vicariously. In fatigue we may imagine an organism as clogged with its own slack, so that restored equilibrium is a matter of elimination. In exhaustion the muscular tissue has perhaps run out of glycogen, or the adrenals and other structures can no longer supply adrenalin. At a meeting of the United Berlin Medical Societies on March 23 (*Muenchener medizinische Wochenschrift*, May 4), Brugsch recognized in war exhaustion a special affection due to the cooperation of psychic and sensory insults, lack of nutrition (due to failing appetite), and excessive bodily exertion. These subjects may recover readily if they can sleep for three or four days at a stretch. There may be severe sequelæ, as persistent low blood-pressure, psychasthenia, myasthenia, and ready disposition to infection. Tuberculosis is often lighted up. The sequelæ are largely dependent on the fact that adrenalin production is still in abeyance. Until it is restored recovery is impossible. The deep-seated nature of exhaustion is shown by the fact that a similar picture develops in cancer patients.

Tetanus and Yawning.

In Gowers' work on "Nervous Diseases" attention was called many years ago to a certain parallelism between the order of participation of the muscles in the act of yawning and in that in the development

of tetanus. The yawn begins as a prolonged inspiration with depression of the lower jaw; next appear brief tonic contractions of the muscles of inspiration, the depressors and elevators of the lower jaw, and certain muscles of the face and neck. If the yawner happens to be standing there is also a slight contraction of the back muscles. These muscles are the ones first involved in tetanus, so that some peripheral nerve center may be invoked to account for the parallel. At a session last March of the Royal Imperial Medical Society of Vienna (*Muenchener medizinische Wochenschrift*, May 4), Beer, after corroborating the observations of Gowers, expressed the opinion that such a center should exist in the velum palati. This not only presides over the mechanism of the ordinary yawn, but is also in evidence in a variety of other phenomena, such as the preagonal yawn of the drowning. The position of this center at the entrance of both the respiratory and digestive tracts make the order of participation of the muscles in part an accidental one.

News of the Week.

Committee of American Physicians for the Aid of the Belgian Profession.—Dr. F. F. Simpson, treasurer, 7048 Jenkins Arcade Building, Pittsburgh, Pa., reports the following contributions received during the week ending July 10, 1915:

S. E. B., Pittsburgh, Pa.	$50.00
Dr. George B. Broad, Syracuse, N. Y.	10.00
Dr. Winfred Wilson, Memphis, Texas	11.50
Delta County Medical Society, Escanaba, Mich.	10.00
Receipts for the week ending July 10	$81.50
Previously reported receipts	7,544.34
Total receipts	$7,625.84

American Red Cross Workers Insulted in Vienna.—It is reported in *The Sun* that the surgeons and nurses attached to the American Red Cross unit in Vienna have been repeatedly insulted and mobbed by the Austrians because they speak English. They are evidently not wanted and their most sensible and dignified course would be to leave. In Russia, Serbia, and France Americans on errands of mercy have been gratefully welcomed and honored even though they did speak their mother tongue.

Typhus Decreasing in Serbia.—A number of American physicians and nurses from Serbia arrived in Paris on July 3 and reported that the epidemic of typhus in that country is practically under control. Dr. Strong and a large staff of Americans are still in Serbia, but it is not expected that they will remain much longer.

Few Amputations Indicated.—In reply to a question in Parliament recently the British under-secretary of war stated that in only 782 cases had it been necessary to amputate one or more limbs of British soldiers admitted to hospitals in England and France since the commencement of the war to the present time. This seems hardly credible when we learn that the French Government states that there are about 15,000 French soldiers in need of artificial legs. This statement was made to the artificial leg department of the American Relief Clearing House in Paris recently organized by Charles Carroll of Carrollton. Dr. Tuffier, it is said, has undertaken to make the necessary measurements, which will be forwarded to New York together with photographs of plaster casts of the stumps.

Health of New York City.—The Department of Health reports that there were, during the week ending July 3, 1,247 deaths in this city as compared with 1,160 deaths during the corresponding week of last year, the rate being respectively 11.20 in 1915 and 10.84 in 1914. While it is true that there were 87 more deaths, the increase in the population accounts for 47 of these. Moreover, the rate for the first 27 weeks of this year remains lower than the rate for the corresponding rate for 1914. Of the contagious diseases, measles showed a decided increase over last year. Both lobarpneumonia and bronchopneumonia and tuberculosis also showed a marked increase over the corresponding week last year.

The University of Vermont Medical School graduated a class of forty-one the last week of June.

St. John's Guild Floating Hospital.—The *Helen C. Juillard*, the floating hospital of St. John's Guild in New York, began her trips for the season on July 6. The boat starts from East River piers on Mondays and Thursdays, North River piers on Tuesdays and Fridays, and Brooklyn piers on Wednesdays and Saturdays.

Fewer Railway Casualties.—Reports made to the Interstate Commerce Commission by the steam railways of the country covering the quarter ending March 31 shows that 65 persons were killed and 1,972 injured in train accidents for the quarter. Compared with the same period the preceding year this was a decrease of nearly 50 per cent. in the fatalities and of more than 5 per cent. in the accidents causing injuries. There was also a considerable decrease in the number of other accidents, including those of employees engaged in railway work and to employees engaged in other work than the operation of trains, classed as "industrial accidents."

Increase in Fourth of July Accidents.—The Department of Health states that there were no fatalities attending the celebration of Independence Day in this city, but there was an increase in the number of accidents of more than 100 per cent over last year, most of the wounds being caused by blank cartridges.

Qualification of Health Officers Under the State Board.—The New York State Public Health Council has voted that local health officers appointed after November 1, 1916, shall have the following qualifications: (1) They shall be graduates of medicine of not less than three years' standing; (2) They shall when appointed be not less than twenty-four nor more than sixty-five years of age; (3) They shall have complied with one of the following requirements: (a) They shall have taken a correspondence course in public health of one year with at least one week of practical demonstrations in laboratory and field work, both correspondence course and demonstrations to be approved by the Public Health Council, with examinations and a certificate; (b) They shall have taken a course in public health of at least six weeks, including practical laboratory and field work with lectures and reading at an educational institution, such course to be approved by the Public Health Council, with examinations and a certificate; (c) They shall have submitted evidence satisfactory to the Public Health Council of special training or practical experience in public health work, with examination if required by the council. Under special conditions, however, speci-

fied in writing by the local board of health or other appointing power or by the health officer, any of these qualifications may be waived by the Public Health Council. The council has also recommended to boards of health that in appointing health officers previous to November 1, 1916, they specify that the appointee agrees to conform to the requirements within the first year of the new term.

Homeopathic Department in the University of California.—According to *Science* the Hahnemann Medical College of San Francisco has offered to convey all its property to the University of California, and has proposed to cease separate instruction. Instead two professorships are to be maintained in the University of California Medical School in homeopathic materia medica and in homeopathic therapeutics, the financial provision therefore to be made, for the next two years, by the homeopaths. The instruction in homeopathic materia medica and homeopathic therapeutics will be offered as elective courses. In all other respects students wishing eventually to become homeopathic practitioners will receive exactly the same instruction in the University of California Medical School as its other students.

Dr. Lucius P. Brown, head of the Tennessee Pure Food and Drug Inspection Department, has accepted the directorship of the Bureau of Food Inspection, New York City Department of Health.

Dr. W. F. R. Phillips of the Medical Department of the University of Alabama, Mobile, has accepted the chair of anatomy in the Medical College of South Carolina.

Dr. Allen W. Freeman, assistant health commissioner of Virginia, has been appointed epidermiologist in the U. S. Public Health Service.

Dr. W. S. Thayer of the Johns Hopkins Medical School has been elected an overseer of Harvard University.

Dr. Roger S. Morris of the Clifton Springs Sanatorium has been tendered the position of professor of internal medicine at the University of Cincinnati. The chair is the recently established Frederick Forchheimer memorial professorship.

Norwegian Hospital, Brooklyn.—The Board of Managers of the Norwegian Hospital, Brooklyn, has decided to build an addition to the institution at a cost of $100,000. The addition will be five stories in height and will cover almost as much ground as the old hospital proper.

Blindness in the United States.—A recently issued bulletin of the Census Bureau reports that blindness is less common in America than in most other countries, and is apparently decreasing among the young. Indians suffer much more than other races from the affliction, and blindness is much more prevalent among negroes than among whites, and among men than women. The blind population of the United States in 1910 numbered 57,272, or 62.3 to each 100,000 of population. Trades taught in schools or workshops have prepared 1,500 blind persons for total or partial self-support.

Charitable Bequests.—By the will of the late Phebe A. Brown of Philadelphia the sum of $5,000 is bequeathed to the Presbyterian Hospital for the endowment of a free bed to be known as the "William Snow Brown Bed." By the will of the late Samuel Dickson of Philadelphia the sum of $50,000 is bequeathed to the trustees of the University of Pennsylvania to constitute the Fanny Hazzard Dickson Fund and one-half of the income from which is to be applied to the maintenance of the William Pepper Laboratory of Clinical Medicine and the remaining half to be applied in the discretion of the trustees to the uses of the Latin and Greek departments.

Appointments at the Rockefeller Institute.—The Board of Scientific Directors of the Rockefeller Institute for Medical Research announces the following appointments and promotions: *Associates*—Dr. James B. Murphy (Pathology and Bacteriology), Dr. Carrol G. Bull (Pathology and Bacteriology), Dr. Frederick S. Jones (Pathology and Bacteriology), Dr. Clarence J. West (Chemistry), Dr. Michael Heidelberger (Chemistry), Dr. Frederick M. Allen (Medicine), Dr. Oswald T. Avery (Bacteriology), Miss Angelia M. Courtney (Chemistry), Dr. Eduard Uhlenhuth (Experimental Biology), Dr. Carl Ten Broeck (Animal Pathology). *Assistants*—Dr. Harold K. Faber (Pathology and Bacteriology), Mr. Chester H. Allen (Chemistry), Mr. James K. Senior (Chemistry), Mr. Glenn E. Cullen (Chemistry), Miss Mariam Vinograd (Chemistry), Dr. R. Werner Marchand (Animal Pathology), Dr. Herbert D. Taylor (Pathology and Bacteriology), Dr. Oswald H. Robertson (Pathology and Bacteriology), Dr. Reginald Fitz (Medicine), Dr. Arthur L. Meyer (Physiology and Pharmacology). *Fellow*—Mr. Ernest A. Wildman (Chemistry).

Changes at the Philadelphia General Hospital.—Dr. George M. Boyd and Dr. Wilmer Krusen have resigned as obstetricians and Dr. Frank C. Hammond and Dr. John A. McGlinn have been appointed their successors. Dr. Henry W. Stelwagon has resigned as dermatologist and Dr. Henry K. Gaskill has been appointed his successor. Dr. Isaac H. Jones has been appointed laryngologist, Dr. James K. Young orthopedic surgeon, Dr. Alexander Uhle genitourinary surgeon, Dr. William J. McKinley oral surgeon, Dr. Robert J. Hunter laryngologist to the tuberculosis department, Dr. Cornelius T. McCarthy assistant laryngologist to the tuberculosis department, Dr. George Wilson assistant physician. Dr. G. S. Crampton has resigned as assistant ophthalmologist and Dr. B. F. Baer, Jr., has been appointed his successor. Dr. Theodore LeBoutillier has resigned as assistant pediatrist and Dr. Charles V. Dorwarth has been appointed his successor. Dr. Harry C. Fish has resigned as assistant physician to the tuberculosis department and Dr. Thomas Kline has been appointed his successor. Dr. John F. X. Jones has resigned as assistant surgeon and Dr. Henry Winsor and Dr. Thomas Shallow have been appointed his successors. Dr. Thomas G. Aller and Dr. David Budin have resigned as assistant oral surgeons. Dr. George Wilson and Dr. Wilson G. Wood have resigned as registrars and they have been succeeded by Dr. Leon Solis Cohen, Dr. J. Morton Boice, Dr. Clarence N. Smith, Dr. J. Ralston Wells, Dr. David W. Kramer, Dr. Russell S. Boles.

Medical Society Elections.—The American Academy of Medicine, at its annual meeting in San Francisco the last week in June, elected the following officers: *President*, Dr. George A. Hare of Fresno, Cal.; *Vice-Presidents*, Dr. Reuben Peterson of Ann Arbor and Dr. R. W. Corwin of Pueblo; *Secretary*, Dr. Helen C. Putnam of Providence, R. I.; *Treasurer*, Dr. Charles McIntyre of Easton, Pa.; *Assistant Secretary*, Dr. W. L. Estes, Jr., of South Bethlehem, Pa. The next annual meeting will be held in Detroit.

The Fulton County (Ky.) Medical Association, at its annual meeting held at Cayce in May, elected the following officers: *President*, Dr. John Naylor of Cayce; *Vice-President*, Dr. Fred Paschall of Fulton; *Secretary*, Dr. Seldon Cohn of Fulton; *Delegate to the State Association*, Dr. H. E. Prather of Hickman.

The Essex South (Mass.) Medical Society held its annual meeting in DeLand in May, elected the the following officers: *President*, Dr. G. M. Kline of Hathorne; *Vice-President*, Dr. W. G. Phippen of Salem; *Secretary*, Dr. H. P. Bennett of Lynn; *Treasurer*, Dr. G. Z. Godell of Salem; *Librarian*, Dr. C. M. Cobb of Lynn; *Commissioner of Trials*, Dr. J. E. Simpson of Salem.

The Florida State Medical Association, at its annual meeting in DeLand in May, elected the following officers: *President*, Dr. R. H. McGinnis of Jacksonville; *First Vice-President*, Dr. W. R. Stevens of DeLand; *Second Vice-President*, Dr. Mary Freeman of Perrine; *Third Vice-President*, Dr. Coffie of Fort Mead. The next annual meeting will be held in Arcadia.

The Medical Society of New Jersey, at its 149th annual meeting held in Spring Lake the last week of June, elected the following officers: *President*, Dr. William J. Chandler of South Orange; *Vice-Presidents*, Drs. Philip Marvel of Atlantic City, William G. Schauffler of Lakewood, and T. W. Harvey of Orange; *Secretary*, Dr. Thomas N. Gray, East Orange.

The Kentucky Valley Medical Association, at its annual meeting in Winchester during the last week of June, elected the following officers: *President*, Dr. W. B. McClure of Lexington; *Vice-President*, Dr. W. H. Martin of Clay City; *Secretary and Treasurer*, Dr. J. H. Evans of Beattyville. The next meeting will be held in Richmond.

The Eleventh District (Texas) Medical Association, at its annual meeting in Palestine on June 24, elected the following officers: *President*, Dr. E. B. Parsons of Palestine; *Vice-President*, Dr. Davidson of Buffalo; *Secretary and Treasurer*, Dr. Vaughn of Tyler.

The Aroostook County (Maine) Medical Association met in annual session at Houlton the latter part of June and elected the following officers: *President*, Dr. H. F. Kalloch of Fort Fairfield; *Secretary*, Dr. W. G. Chamberlain of Fort Fairfield.

Obituary Notes.—Dr. Robert E. Swigart of New York, a graduate of the Cleveland College of Physicians and Surgeons, Cleveland, Ohio, in 1898, and general superintendent of the medical department of the United Fruit Company, died suddenly from apoplexy on June 27, aged forty-one years.

Dr. Hiram Owen Worthen died at his home in Barre, Vt., on June 13 at the age of 77 years. He was graduated from the University of Vermont Medical College in 1869.

Dr. John M. Hastings of Boston died at his summer home in Provincetown on June 11. He was born in Bangor, Me., and was graduated from the Hammond Medical School in the class of 1895.

Dr. Henry Janes of Waterbury, Vt., died June 16 at the age of 83 years. He was a graduate of the College of Physicians and Surgeons, New York, in 1855. He retired from practice a number of years ago.

Dr. Henry Otto Hoffmann of Brooklyn, N. Y., died on June 25 at the age of 76 years. He was born in Germany and received his degree from the University of Würzburg in 1872. Soon after graduation he came to this country and practised for ten years in Cleveland, Ohio, afterward removing to Brooklyn, where he had since resided. He was a member of the Kings County Medical Society and the Long Island Medical Association.

Dr. Robert N. Ramsay died at Philadelphia on June 16 at the age of 58 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1879. For a time he practised his profession at Mahanoy City, Pa., later going to Birmingham, Ala., and finally settling in Philadelphia. He was a member of the Philadelphia County Medical Society and of the Medical Society of the State of Pennsylvania and a Fellow of the American Medical Association.

Dr. Eugene I. Santee died at Philadelphia on June 16 at the age of 70 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1866.

Dr. Samuel Weiss died at Lebanon, Pa., on June 17 at the age of 70 years. He was graduated from Bellevue Hospital Medical College in the class of 1870.

Dr. James E. Cleaves of Medford, Mass., died June 20 at the age of 62 years. He was born in Somerville and was graduated from the Harvard Medical School in 1879. After practising for a few years in Amesbury he went to Medford, where he had lived for 35 years. He was for some time chairman of the Board of Health of that city, and was a member of the council of the Massachusetts Medical Society and also a member of the Medford and the Middlesex Medical Societies.

Dr. J. Walter Bean of Medford, Mass., died suddenly on June 21 at the age of 60 years. He was born at Sutton, N. H., and was a graduate of the Medical Department of the University of Vermont in 1882. He served a term as interne at Bellevue Hospital, New York, and then began practice in Lyme, N. H., but in a few years moved to West Medford, Mass. He was a member of the Medford Medical Society and was for many years a member of the Medford Board of Health, in association with Dr. Cleaves who died the day before he did, and was for some time its chairman.

Dr. George P. Sword of Huntington, L. I., a graduate of the New York Homeopathic Medical College and Hospital, New York, in 1888, died at his home suddenly on July 2, aged fifty-two years.

Dr. Charles Adams Stewart of Duluth, Minn., a graduate of the College of Physicians and Surgeons of Keokuk, Iowa, in 1870, and a member of the American Medical Association, the Michigan State Medical Association, the St. Louis County Medical Society, and the Western Surgical Association, died in Minneapolis, after a long illness from paralysis, on June 22, aged sixty-seven years.

Dr. Rebecca V. Combs of Columbus, Ohio, a graduate of the Ohio Medical University, Columbus, in 1896, and a member of the Ohio State Medical Association and the Columbus Academy of Medicine, died suddenly on June 20, aged sixty-three years.

Dr. George H. Zimmerman of Pocahontas, Va., a graduate of the Medical College of Virginia, Richmond, in 1880, died at his home after a long illness, on June 23, aged fifty-seven years.

Dr. Horace F. Livingood of Womelsdorf, Pa., died at Jefferson Hospital, Philadelphia, on June 25 at the aged of fifty-six years. He was graduated from Jefferson Medical College in the class of 1882.

Dr. Mary Elizabeth Nowell died of pneumonia at Altoona on June 25 at the age of seventy-two

years. She was graduated from the Woman's Medical College of Pennsylvania in the class of 1884. She was a member of the Blair County Medical Society and of the Medical Society of the State of Pennsylvania and she was a Fellow of the American Medical Association.

Dr. THOMAS HEWSON BRADFORD died in the sequence of an operation at the German Hospital, Philadelphia, on June 25 at the age of sixty-seven years. He was graduated from Jefferson Medical College of Philadelphia in the class of 1874, and he had served as interne in the Pennsylvania, Howard, and Children's Hospitals. He was chief medical director of the Philadelphia Life Insurance Company. He was a member of the Philadelphia County Medical Society and of the Medical Society of the State of Pennsylvania and a Fellow of the College of Physicians of Philadelphia and of the American Medical Association.

Dr. MENOTTI MAZZA died at Philadelphia on July 4 at the age of 46 years. He was graduated from Keokuk Medical College, College of Physicians and Surgeons in the class of 1906.

Dr. VICTOR ALBERT ELLSWORTH of Boston, Mass., a graduate of the University of Buffalo, Medical Department, in 1896, for twenty-one years superintendent of the Washington Home in Boston, and a delegate to the International Temperance Congress at Stockholm in 1907, and to The Hague Temperance Congress in 1911, died at his home on July 7, aged 69 years.

Dr. WILLIAM GIBSON FLOYD of Roanoke, Ala., a graduate of the University of Maryland, School of Medicine, Baltimore, in 1878, a member of the Medical Association of the State of Alabama, and a member and former president of the Randolph County Medical Society, died at a sanatorium in Atlanta, Ga., on June 26, aged 63 years.

Dr. J. A. JOHNSON of Atlanta, Ga., a graduate of the Atlanta Medical College in 1855, died at his home on June 30, aged 79 years.

Dr. BENJAMIN FRANKLIN STALKER of Borden, Ind., a graduate of the University of Louisville, Medical Department, in 1873, died at his home on June 25, aged 69 years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

ST. GEORGE'S HOSPITAL—THE NEW MILITARY HOSPITALS—LEPROSY—ROTUNDA PATHOLOGICAL REPORT—DUBLIN ACADEMY—PLAGUE BACILLI—RED CROSS AND ST. JOHN'S SOCIETIES—FARMERS SELL ANIMALS OVER AND OVER—THE LATE DR. CARMICHAEL.

LONDON, June 26, 1915.

ST. GEORGE'S Hospital occupies one of the most prominent positions at the west end of London. From Hyde Park corner it faces full on the park and enjoys the view of the constant movement of the fashionable world. The value of the site is immense and it has often been remarked that its sale would produce an endowment for the hospital. At one time, in fact, power to dispose of it for this purpose was obtained from Parliament. The matter was referred to at the annual court of governors on the 17th inst. when it was said that on several occasions there had been some negotiations, but no one has made an offer which the committee could recommend to be accepted. They are at present considering whether it would not be well to carry out several improvements while waiting quietly for an offer of such a sum as would reach their expectations—more especially as the value will probably increase as time progresses.

The staffing of the five great military base hospitals just organized in London to prepare for the reception of the wounded has given rise to some sharp criticism. The medical officers are to have the rank of major and each severally to exercise complete control. But it seems that civilians and military officers will both be employed, and some people think they will not be likely to work well together. But the suggestion is unworthy and is not the real reason of differences alleged to have been met with already. The military may be dominant, but if they insist on so much time a day being passed in their hospitals, they can hardly expect civil practitioners to offer to assist them.

A case of leprosy—the tuberculated form—was shown by Dr. C. M. O'Brien at the Dublin Academy and Sections from a nodule were exhibited (prepared by Mr. T. T. O'Farrell) in which numbers of bacilli were seen. Some of these were in cells, but most of them were extracellular. The patient was a retired soldier who had offered to serve again, but was refused on account of a cutaneous eruption. He had served in Malta, Bermuda, Jamaica, and South Africa and left the army in 1906 and worked as a farm laborer. In 1913 he suffered much from boils. In 1914 the case was diagnosed and was at the meeting fairly obvious. Face broad, chin prominent, nose flattened, lips thick, forehead lumpy and shiny, hands grey and swollen, glands shotty, mucous membranes free, no anesthesia. Dr. O'Brien reported Wassermann reaction was positive and no reaction with alt-tuberlin injected subcutaneously or by von Pirquet's method.

At the previous meeting of the Academy Dr. Rowlette read the pathological report of the Rotunda Hospital for the past year. It was stated that 774 specimens had been reported on, including 128 fragments removed for the purpose of diagnosis; there were 169 operation specimens and 25 of lochia from septic cases. Vaccines were used extensively in the gynecological as well as in the obstetrical wards. A fatal case of acute yellow atrophy was related in full detail. The following specimens were exhibited: embolus in the pulmonary artery, naevoid polypus of cervix, sarcomata uteri, fibrosed uterus, malignant papillomata of ovary, malignant of ovary, fibroma of ovary thrombosed ovarian vein, fibroma of rectus muscle, retroperitoneal sarcoma.

Professor McWeeney (in the chair) said as to vaccines they were frequently used with good results when the organism was different from the one affecting the patient. He knew this was very heterodox doctrine, but he was led to it by experience. As to yellow atrophy of the liver naked eye appearances were not always striking. He had seen multi-nucleated giant cells scattered through sarcomatous polyo of the uterus.

Sir William Smyly was interested in the case of myoma with sarcoma, from having met a similar one. The myoma was removed and the uterus explored, but the sarcoma not found. Profuse hemorrhages continued and curetting tried when the sarcoma was found. He felt confident cancer at an early stage could be cured by operation, more especially cancer of the body of the uterus.

Dr. Neill's experience of vaccines in septic cases was favorable, and mentioned a case of pre-puerperal infection in which they seemed to save life.

Dr. O'Farrell asked if a particular type of endometritis was prone to malignant change, though at the time not cancerous. Also if differences in rate of growth on agar of staphylococci had been observed in comparison with the ordinary pyogenes. He had seen a staphylococcus grow so slowly as to resemble a culture of streptococcus in forty-eight hours.

Dr. Rowlette in replying stated the custom at the Rotunda to be as soon as sepsis appeared a dose of vaccine from a previous case was given and at the same time cultures were started to produce an autogenous vaccine. Stock vaccine gave a good result, but their practice was to have the autogenous ready for the second dose when possible. He did not think there was any relation between endometritis and malignancy. He had not seen a patient return with malignant tumor whose endometrium had previously been pronounced non-malignant. He hoped the extended use of vaccines would not lead to the neglect of other treatment.

Dr. Sheldon of Burma has sent a note to the *Lancet* on plague bacilli in an unusual position. An adult Burman died before medical aid reached him, after an illness of 36 hours. Specimens of peripheral blood and of cerebrospinal fluid were taken and stained. The former, when he examined the slide, showed plague bacilli in small numbers, but the "slides of the cerebrospinal fluid simply swarmed with them."

The joint fund of the Red Cross and the St. John's Ambulance Societies now exceeds a million and a half sterling. A feature of this collection has been organized efforts in various trades. The farmers in Bucks had a sale for the Red Cross in the cattle market, High Wycombe, at which a number of animals were sold several times over. The amount raised thus was over a hundred pounds. The British Farmers' Red Cross Society has further established a hospital for enteric disease at Calais at a cost already of £8,000. This fund has also presented two complete hospitals to Serbia and proposes to devote, as soon as collected, £20,000 to the help of the wounded British soldiers at the Dardanelles.

The City Corporation has established, in conjunction with St. Bartholomew's Hospital, a free dispensary at which workers in the city, whether residents or not, who are attacked with any form of tuberculosis may obtain advice and treatment free on Tuesdays and Fridays. A special clinic will be held on Thursday evenings for the investigation of important or difficult cases.

Dr. E. W. Scott Carmichael, who died on the 12th inst. at the age of 42, was the third Dr. Carmichael who practised in Edinburgh—the third, in fact, in direct descent, for both his father and grandfather held prominent medical positions in the Scottish capital. The late deceased practised both surgery and gynecology which, at one time, some strict specialists maintained, was rather objectionable.

Amenities of Mexican Warfare.—It is reported in El Paso that a band of revolutionists set fire recently to the Tively Hotel in Chihuahua, which was occupied as a base hospital by the Villistas, and burned to death 300 of the occupants, some 200 of the less severely wounded escaping.

4. Homogenized Milk in Infant Feeding.—Maynard Ladd states that the homogenization of liquids of different densities consists in reducing the constituent elements into such a physical condition that they will no longer separate, but will maintain a permanent and even composition throughout the mixture. Briefly stated, this result is brought about by a powerful pump which forces the mixture through a finely ground agate valve against great pressure. After its passage, the mixture is perfectly homogeneous, and in the case of milk, or mixtures of milk and oils, the fat globules are crushed, torn, and pulverized and so incorporated with the other elements of the milk, that they can no longer rise by action of gravity, separate after long standing, or agglutinate. The mechanical device by which this result is made possible is the invention of M. A. Gaulin of Paris. His first machine was brought out in 1899. Homogenization improves decidedly the taste of the milk or cream, particularly that of pasteurized milk. As the process prevents the separation of the fat, homogenized creams can be readily pasteurized. When commercial milk is to be transported long distances in warm weather and its temperature allowed to rise from lack of proper refrigeration, the continual jolting to which it is subjected causes the cream to be churned into butter fat, and it is impossible to reincorporate it into the milk in its original form. The process of homogenization has a beneficial effect upon the keeping qualities of milk. The author has carried on a series of clinical experiments in order to show that vegetable oils, such as olive oil, are readily digested and assimilated when homogenized with skim-milk in cases of intolerance to cow's milk fat. By using a chemically pure precipitated casein, one can combine pure casein with pure oils and pure sugars of different varieties, adding artificially prepared mineral matter in varying proportions. Such mixtures, homogenized, may be found to be of use in exact metabolism experiments, although they would be too expensive and complicated for practical feeding. One may combine a vegetable fat, such as olive oil, with precipitated casein, or fat-free lactic acid milk, and test its food value in acute diarrheas, or in convalescents from acute diarrheas, conditions in which the ordinary fats of milk are not well tolerated. A more practical problem at once suggests itself in mixtures of olive oil and skim milk—especially in combination with the malt soup mixtures. The type of food which the author has found most useful in cases of fat indigestion with extreme malnutrition, is the malt soup mixture. Many of the worst cases are amenable to successful feeding by this method intelligently applied.

5. Luetic Bursopathy of Verneuil.—W. P. Coues reports a case of the congenital type of this condition. He states that there are two forms of gummatous bursitis, which may exist in congenital as in acquired syphilis, one by extension of specific disease from neighboring parts, the bones and joints, and the other class, to which the reported case belongs, primary in the bursa itself. Syphilis of the bursæ is probably often

unrecognized. The disease must be differentiated from subperiosteal abscess near the joints (specific osteomyelitis) and from congenital specific arthropathies, such as Clutton's disease. Radiographs will be of great aid in differentiating this trouble from true specific bone disease. The Wassermann test—contrary to the general idea that it is 100 per cent. positive in congenital syphilis—may be negative. An *x*-ray examination of the shin bones should always be made (lateral view) when there is a question of specific bursitis, as well as a Wassermann test. The *x*-rays will often give the more valuable information of the two. Traumatism brings the condition to activity. An indolent bursitis in a child, particularly in such localities as the elbow or knees, with or without traumatism, and with or without obvious signs of congenital specific disease, should arouse suspicion that one is dealing with a luetic bursopathy of Verneuil, and lead to further study of the case, with this in view.

6. New Symptoms in Amaurotic Family Idiocy.—I. H. Coriat calls attention to some phenomena in this disease which have been either completely overlooked or only briefly described. Explosive laughter was noticed in three cases. In two of these the mental deterioration was marked. In the first case the symptom appeared about seventeen months after the onset of the disease; in the second case it began as one of the initial symptoms and ceased about ten months later, at which time the child was taken ill with scarlet fever. In the third case it was noticed about six months after the mental dullness first appeared. Whether this explosive laughter is a sign of the mental deterioration, as sometimes occurs in multiple sclerosis or dementia præcox, or due to some thalamic lesion, is impossible to definitely state at present. Hydrocephalus was present in one of the author's cases, and in one case each reported by Huysmans and Sachs and Strauss. Bulbar symptoms were present in one case and were shown by drooling of saliva, choking spells, difficulty of swallowing, and attacks of apnea. This child died suddenly from bulbar paralysis. Constant lateral and rotary nystagmus was present in three cases, in one of which it persisted during the entire course of the disease. In two cases there was a marked flaccidity of the limbs, resembling the condition seen in amyotonia congenita (Oppenheim). Attention was first called to this symptom in amaurotic family idiocy by Kowarski in some cases reported from Wilna, Russia. Increased reflex reactions to sound and touch are among the most interesting phenomena of this disease. The unusual sensitiveness to sound (hyperacuisis), which is so characteristic, has long been known and appears to be present in nearly all cases, at least in the early stages, although it may disappear with the increasing mental weakness. Another abnormal reflex phenomenon is increased sensitiveness to light or to tactile stimuli. For instance, plantar stimulation may cause a tremor of the stimulated leg, or a rhythmical contraction of the quadriceps muscle, both of which may be of longer duration than the stimulus itself. A contralateral knee jerk reflex has also been observed, and like the plantar phenomenon, this consists of a rhythmical contraction of the opposite quadriceps and is of longer duration than the initial reflex itself. The explanation of these abnormal reflex signs is rather difficult. The phenomena are probably irradiative and show that certain inhibitions in the receptive mechanisms of the central nervous system are at fault.

1. Cancer of the Mouth.—Robert Abbe has studied the histories of the last one hundred cases of mouth cancer seen in private practice. This group chosen from hundreds of cancer cases in all parts of the body, has been observed during the past eighteen months. Without prejudice he has tried to find a common cause. The tongue showed cancer, or a precancerous condition, in thirty-six; inside of cheek, fifteen; gum, twenty-one; lip, fourteen; throat, fourteen; total, 100. Of women there were ten, men ninety. Of the ninety men, *all* were heavy smokers, except one who had a cancer of the lip, in a scar from an old baseball injury. Almost every man had been an inveterate smoker of from three to twenty cigars daily. One denied cigars, but acknowledged one or two packages of cigarettes daily; he had cancer of the tongue. The tongue cases showed strikingly that irritation was the cause. Thirty-three of the thirty-six cases were inveterate smokers, some of as many as twenty cigars daily. Many used a pipe, which often caused cancer to begin where the pipe end allowed the hot smoke to come upon the tongue. It seemed to the author in former years he had never seen tongue cancer in cigarette smokers, but in reviewing his carefully taken notes of patients' statements, he finds six among thirty-six tongue cancers were in smokers of cigarettes only. In conclusion, the author places emphasis on the prolific cause of all forms of cancer of the mouth from incessant irritation, notably from tobacco; a terrible and unnecessary toll on human life! If one must use tobacco at all, a moderate and not abusive amount may not be injurious; but it stands proved that in any form it may be disastrous.

3. Surgery in Carcinoma of the Stomach.—J. B. Deaver states that the operation of choice is subtotal gastrectomy with wide excision of involved glands and a posterior gastroenterostomy. Polya's new operation, of bringing a loop of jejunum through the transverse mescolon and anastomosing it to the proximal end of the cut stomach in its entirety, holds out the possibility of a greater area of extirpation. The mortality of gastrectomy is high at present, but with increased diagnostic skill and earlier operations one may hope to approach the mortality of other major surgical work. A gastroenterostomy done for pyloric cancer is a poor makeshift, and unless performed for relief of obstruction only in an inoperable lesion, is worse than useless and reflects little credit on the surgeon. The end results of operation upon carcinoma of the stomach at present suffer from the fact that most cases are operated on at the late incurable stages. The combined statistics of the large clinics indicate that from 20 to 30 per cent. of all patients having undergone gastrectomy for carcinoma of the stomach, will live more than three years after operation, and that from 10 to 20 per cent. will be alive at the expiration of the five-year period. That these figures can be much improved by earlier surgery there can be no doubt. Finally, one should operate in all cases of cancer of the stomach, operate early, and, if unable to make a diagnosis, operate to make it.

5. Cancer in Relation to Body Elimination.—L. Duncan Bulkley notes that in cancer there are evidences of

faulty metabolism and faulty body elimination. These errors may be observed not only in advanced and recurrent cases of cancer but also in those which are in very early stages; indeed their occurrence in recently forming cancer and in patients soon after operation forms a strong argument for their causative relation to the disease. The evidences of imperfect metabolism and faulty body elimination in cancer are found in the condition of the blood, and in the excretions from the kidneys, bowels, and skin; and minute and careful study will seldom fail to detect these departures from normal in patients with this disease.

7. **Radium in Carcinoma of the Uterus.**—W. S. Newcomet concludes that while radium cannot be recommended as an agent to control carcinoma of the uterus, as there is no evidence to show that it controls metastasis, it does inhibit its local growth in many cases, and even advanced cases can be temporarily restored. With the evidece of the complete disappearance of the disease, the general improvement of the system can scarcely be laid to a psychical impression. Therefore, the more general use of radiation in cases of uterine carcinoma is to be recommended, especially as a postoperative procedure.

1. **Closed Ether and a Color Sign.**—J. Bryant and Y. Henderson point out that the same general facts and the same character of direct evidence which have established rebreathing as a proper and beneficial adjunct of nitrous oxide in general anesthesia demonstrate the advantages of rebreathing and the use of closed methods also in the administration of ether. Many of the special advantages claimed for nitrous oxide as compared with ether are probably due to the fact that the former is now generally administered by rebreathing methods, and the latter by open methods, rather than to the particular qualities of the two anesthetics themselves. Evidence is adduced to show that to a very large extent the depression of the circulation and respiration, and the postoperative nausea, vomiting, intestinal paresis, and gas pains incidental to etherization by open methods are the results of acapnia. On this account the authors urge the adoption of closed and rebreathing methods, the preliminary administration of morphine and atropine, and avoidance of fear and excitement. The Rovsing mask and bag afford a satisfactory and efficient method of controlling the rebreathing and rate of ether administration, combined with the utmost simplicity. The principal point made by the authors is that by observing the color of the skin it is possible to estimate the condition of the circulation. Pallor under ether usually indicates a circulation depressed because of acapnia and needing to be restored and maintained by more rebreathing and conservation of the body's store of carbon dioxide. Excess of rebreathing and deficiency of oxygen are indicated by a cyanotic tint. The rule for the anesthetist is: Keep the patient pink.

2. **Bacteriology of the Urine in Nonsuppurative Nephritis.**—George F. and Gladys R. Dick review the literature of this subject and report the results of their own investigations. They find that the organisms which are peculiar to nephritic urine for the most part are classed as small gram-negative or gram-positive anaerobic, pleomorphic bacilli. They are cultivated with considerable difficulty. They grow without hemoglobin, but not without ascites or serum. They are strict anaerobes. They resemble closely the bacilli described by the authors in anaerobic cultures of the throat, blood, and urine in scarlet fever in which nephritis is so common. In four cases these organisms were found in pure culture. Two of the cases lacked both streptococci and the small, pleomorphic organisms. The peculiar anaerobic, curved, pleomorphic, gram-positive organism found in these cases somewhat resembled diphtheria bacilli. Experiments show that the bacteria isolated from the urine of nephritis are capable of producing both the urinary and the anatomical findings of nephritis. The excretion of bacteria through the kidneys in focal infections and in acute infectious diseases indicates that both prophylactic and curative measures in cases with positive bacteriological findings should be directed toward removal of foci of infection from which bacteria might enter the blood stream, and when this is impossible, as in the acute infectious diseases, toward minimizing their action on the kidney.

5. **Treatment of Burns of the Extremities.**—C. A. Parker details a method of treatment of burns of the extremities with special reference to the prevention of deformities and the preservation of function. He holds that this is possible with proper treatment in any such burns, however extensive they may be, so long as they are compatible with life. The shorter the time of healing, the less likely they are to occur. In burns involving the whole thickness of the skin there is a slough to be thrown off and this may take three weeks or longer, before the active process of healing has commenced. The cutting away of the slough is dangerous and the burn should be treated during this period with such dressings as can be easily applied and cause least disturbance. The author is inclined to use the plain wet dressing. After the slough comes the aggressive treatment; here skin grafts can be used with various degrees of success, but are frequently ineffective. After the slough comes away, the author treats the wound as an ulcer with adhesive strips until it is finally healed. This does not interfere with skin grafts which can be laid on under the strips. The strips allow moisture to exist under them and are easily removed by inserting the blunt point of the scissors under the edge of the adhesive strips and cutting across all the strips from the bottom to the top, the strips being placed across the limb. Of course there is a flow of pus from the inside of the adhesive plaster but there is very little left remaining on the limb. The plaster prevents exuberant granulations and allows a continuous growth of epithelium from the margins. It does not adhere to the exposed surface, which is always moist. Such as remains after the removal of the plaster can be sponged off, and the plaster renewed as before. Antiseptics must not be used over the wound as they destroy new cells. For the prevention of contractures, fixation of the limb in the proper position constantly during the period of healing is essential, and for this the author uses a plaster-of-Paris cast made in halves so that it can be removed as frequently as necessary to change

the plaster and overlying gauze. This should be changed every day and the adhesive plaster twice a week.

The Lancet.

5. Vaccines in the Treatment of Respiratory Diseases. R. J. Rowlette.
6. X-Ray Localization and the Removal of Foreign Bodies on the X-Ray Table. J. R. Caldwell.

2. Magnesium Sulphate in Treatment of Tetanus.—S. J. Meltzer describes this method of treatment as follows: In subcutaneous infections the dose should not be more than 2 c.c. and not less than 1.2 c.c. of the solution (25 per cent.) per kilogram of body weight, to be injected four times in twenty-four hours. No massage should be used. Light etherization of a morphinization should precede the injection of magnesium. The intramuscular injection and inhalation of ether is based upon the finding by Auer and the author that a moderate inhalation of ether increased considerably the efficiency of magnesium salts. Chloroform does not exert such an effect. The patient should be fairly well etherized, and 2 c.c. of a solution of magnesium sulphate (25 per cent.) per kilogram of body weight is injected into the muscles of the thigh. At the end of the injection the thigh should be massaged and the ether anesthesia continued lightly for about 20 minutes longer. In intravenous injections the concentration of the solution should be about 3 per cent. (isotonic), and not more than 5 c.c. per minute should be permitted to run into the vein. In intraspinal injection the dose to be injected, at the usual place of the lumbar region, should be 1 c.c. (of a 25 per cent. solution) for every 10 kilograms of body weight. Any case of tetanus, mild or severe, should from start to finish be treated by subcutaneous injections about every six hours with doses of magnesium sulphate as described before. Cases having severe attacks should receive in addition an intraspinal injection. This may be repeated when necessary, but the subsequent doses should be slightly smaller than the preceding ones. If the attack contains an element of immediate danger an intravenous injection may be administered. When for one reason or another the intraspinal and intravenous injections are not practicable the intramuscular injection plus ether anesthesia may be resorted to. When treating tetanus by magnesium sulphate preparations for artificial respiration ought to be made in order to be able to use efficient doses of the salt. The pharyngeal insufflation device is the simplest and most reliable method for this purpose. When this device is not at hand, oxygen should be administered by the method of intratracheal insufflation through a tracheotomy wound. The treatment of the failing respiration should be begun at an early stage; asphyxia of the tissues would thus be avoided and a complete restoration could be attained early. The treatment of tetanus by magnesium does not exclude its serum treatment.

3. Cerebrospinal Meningitis.—R. Donaldson reports the results of observations made during an outbreak of this disease in Reading, England. The cerebrospinal fluid from about seventy cases was examined. The author believes that the causal organism, the epidemic, was a diphtheroid rod closely related to the Klebs-Löffler bacillus, of which, indeed, it may actually be a variant, and that one is witnessing, as Sir William Osler says, the struggle of a new disease to win a place among the great epidemics of the world. This diphtheroid rod is an extremely pleomorphous organism and may give rise to Hoffmann-like forms, to what appear to be meningococci, etc. It is probably very widely spread in nature in one of its more resistant forms, and it is this form and not the meningococcal one which is trasmitted from one to another. It is also probably to be found more frequently among individuals than is imagined. The disease may give rise to the most diverse symptoms, evidently due to an actual invasion of the body by the infective agent, and not merely to the action of toxins manufactured locally. It is in this respect that it differs from diphtheria. In other ways, however, there is a certain similarity between the two diseases. The above hypothesis apparently offers an explanation why sera fail so often in the treatment of so-called cerebrospinal meningitis, and the analogy to diphtheria suggests that treatment on similar lines should be adopted.

Berliner klinische Wochenschrift.

May 24, 1915.

The Floating Lung Test.—Schönberg sums up his article as follows: We have the fact, a most striking one, that in a seven months fetus, taken by us from intact membranes, the lung tissue was expanded and contained air. The usual reasons for the presence of the latter could not have obtained. A gas forming infection and putrefaction can also be excluded. In addition to the air, the alveoli contained only a slight amount of the constituents of amniotic fluid, such as epidermal scales. This find has been shown to be quite normal. The fetus in this case had been removed from a woman dead of advanced tuberculosis. During her death agony the fetus, becoming asphyxiated, developed violent respiratory movements, causing negative intrauterine pressure. The possibility that air therewith entered the fetal lungs seems to be the only tangible hypothesis, which, however, is not supported by evidence. The percentage of gases in the amniotic fluid is too insignificant to explain the case. As a pure matter of fact, the floating lung test is not absolute evidence that a newly born child has breathed, hence the case is highly significant for forensic medicine.

Treatment of Pleural Suppuration with Irrigation Drainage.—Leschke refers to the 90 per cent. mortality of empyema during the first half of the 19th century in contrast with which we now cure 90 per cent. with siphon drainage and resection of the ribs, resources respectively of the physician and surgeon. Both these procedures have drawbacks. Rib resection involves a large wound, pneumothorax and the elimination of one lung from respiration. Siphon drainage does not completely evacuate all the pus and requires constant supervision and after treatment. Improvements have been introduced such as injecting and then aspirating antiseptic fluids. This resource, however, so changes the antrathoracic pressure that cerebral disorders have resulted. Pressure variations also tear new adhesions and cause hemorrhages. The author has sought to devise a method which shall be free from these drawbacks. He introduces two catheters side by side in separate openings in the pleural opening of the empyema. One is for the maintenance of Bülau's siphon drainage while the other is for irrigation of so smooth a type that neither pressure variations nor compression of the lung can occur. Irrigation may be continuous or consist of three separate flushings daily. These are readily secured by a gravity apparatus. The treatment is controlled by frequent radiograms. The author has thus far used the method in a few cases only.

Experiences with Antipediculosis Remedies.—Löhe

enumerates the following substances which have been tested for this purpose: Ethereal oils and especially anise oil, powdered naphthalin and combinations of the two, and various proprietaries the composition of which is more or less a secret. The latter, in sachets, have been sent in great quantities from the soldiers' home folks to the men at the front. These substances naturally possess drawbacks, and even cause serious lesions, some of which are "punched out" defects in the skin of the genital region, penis, scrotum, anus, axillæ, insides of thighs, etc. Some of these lesions are as large as a penny. They have no indurated base but form shallow crusts, detachment of which is attended by bleeding. According to the uniform tendency the affection begins with itching, and then vesicles appear which rupture and gradually end in ulcer formation. The lesions bear a striking resemblance to chancroids, but a careful search has shown the absence of Ducrey's bacillus. Priess in a very brief communication states that the composition of one of these secret remedies is as follows: Powdered anise, 2; sugar, 1; calcium carbonate, 1; hydrofluosilicate of sodium, 95.

Cholera.—Gildermeister and Baerthlein come to the following conclusions in regard to Asiatic cholera in the present war: A large number of cholera vibriones in the dejecta of cholera patients perish in a few hours, although a not inconsiderable number persist alive in the said dejecta over intervals of up to 30 days. At the same time the intestinal evacuations of many healthy subjects contain living vibriones. In these carriers the latter may be active for several weeks. This survival is probably longer in war because the dejecta are deposited directly on the ground on fields and woods. Every effort should therefore be made to destroy these organisms as soon as they have left the body. For the demonstration of vibriones in the stools the author like the original culture medium of Dieudonne in association with hemoglobin extract in alkaline agar. In the stools of patients and carriers mutation forms of the vibrio have been seen. On the Eastern frontier were often seen mixed infection of cholera and dysentery and cholera and typhoid.

Digestibility of War Bread.—Decker means by war bread wheat flour rolls containing 10 per cent. of rye flour, and rye loaves containing potato flour. In Münich there are also zwieback when recommended by physicians, Graham bread and gluten bread for diabetics. War bread requires more mastication than the best wheat bread, but this cannot be held against it. War rolls if sliced thin and toasted have their digestibility and palatability increased. The rye-potato loaf is the real problem. Some individuals, naturally great bread eaters, consume it in much too large amounts. These should curtail their bread ration. It also helps materially if the bread is allowed to get a little stale. Fresh rye bread even without potato addition will cause bloating especially when taken with beer. Patients without gastric juice react by diarrhea and must be allowed wheat bread. The author recommends bacillary milk cultures for victims of intestinal indigestion, and Graham bread for those with constipation. Generally speaking those with whom war bread disagrees are advised to eat dishes prepared from cornmeal, rice flour, and any other farinaceous meal, in addition to the usual cereals.

May 20, 1915.

Specific Treatment of Typhoid Fever.—Peiper refers to the treatment of this affection with dead cultures of typhoid bacilli. He had practised this as far back as 1891, when eight typhoid patients received small therapeutic doses of bacilli cultures, with the idea of provoking the formation of curative antibodies. Another investigator, E. Fraenkel, made a similar test in 1893 on a large material—fifty-seven patients. Both the author and Fraenkel noted a breaking up of the continued fever and an early apyrexia. Peiper was obliged to discontiue his work, and not until 1914, or twenty-three years later, did he resume it by treating three children with certain typhoid with ordinary immunizing vaccine. Four therapeutic injections were given and within a week full defervescence was secured. The entire duration of the fever was two weeks. As the author has treated from first to last only ten cases of the disease, he can make no claims. There is, however, an undoubted specific activity exerted, as all symptoms showed improvement. Very recently Goldscheider and Aust have independently proceeded along this line of effort and have reported favorable results.

Torsion of the Pedicle in Inguinal Testis.—Jastram writes monographically on this rare accident, which was first described by Nicoladoni in 1885, and is able to add two new cases to the recorded material. Many years ago Enderlen collected and analyzed twelve cases in which the torsion lasted from one to seventy-seven days, apparently with no permanent ill effects. In a case of torsion lasting forty-two days the organ was found gangrenous. The author's patients were operated on two to five days respectively after the symptoms appeared. The onset of the accident is sudden, suggesting an incarcerated hernia of the omentum or intestine. The claim of Tiltmann that this accident always results from a trauma is surely erroneous. A mere change of posture might cause a rotation of the pedicle of a testicle which is undergoing involutional changes as a result of compression. In some of the recorded cases the organ had become flattened. The operation consists of an orchidectomy, the retained testis being a source of danger and of very doubtful value to the economy.

Mercurial Inhalations in the Treatment of Syphilis.—Stümpke appears to be enthusiastic over the power of mercury inhalation in causing the disappearance of the Wassermann reaction, even without the aid of salvarsan. Not sufficient time has elapsed to enable the author to record relapses. Unfortunately, mercury thus given will sometimes lead to certain phenomena of hydrargyrism so that care is required in selection of cases and in general technique. Men bear the treatment better than women. The contact of the mercury with the mouth and throat, especially when the latter are already irritated by the presence of mucous patches, appears to cause a general redness of the mucosa, but the treatment should be continued to a moderate extent and no true stomatitis will develop. The inhaler and method were first described in the preceding number of the *Wochenschrift* by Frankenstein, their inventor. Priority is not claimed, as Kromayer introduced a similar apparatus into practice in 1908. Briefly, the mercurial fumes are obtained by heating tablets of quicksilver amalgam.

Hypertrophy of the Thymus Gland.—Le Boutillier expresses the belief that certain cases of sudden death in infancy are due to tracheal compression by the sudden enlargement of an already hypertrophied thymus, the increase in size being the result of engorgement caused by some circulatory disturbance. The presence of hypertrophy of the thymus is to be suspected when a child is observed to be more or less cyanotic and to suffer from dyspnea without any discernible cause.—*Archives of Pediatrics.*

Insurance Medicine.

THE GENERAL FACTORS DETERMINING MEDICAL SELECTION.

FROM "ALLGEMEINE LEBENSVERSICHERUNGSMEDIZIN" BY PROF. DR. GEORG FLORSCHÜTZ OF GOTHA.

(*Continued from page* 79.)

It still remains to discuss the constitutional factor in definite organic diseases, but we must be brief, in order not to invade too much the special field of life insurance medicine. We recognize the pathological constitution in mental diseases through the fact that slight external irritants, suffice to disturb the brain in its psychic equilibrium and to occasion abnormal reactions with rapidly following states of exhaustion—in the first place through the heart in the peculiar quality of its musculature. But while we are advised in mental diseases to judge, essentially, the constitutional factor solely by heredity and previous disease, the heart *per se* may be judged as to its efficiency by a quantitative test of the myocardium. In recent years there has been very great activity in this special department and new methods have constantly been devised, in order to determine accurately the force of the heart's action, although thus far no one has succeeded in determining in any individual case exactly what the condition of the cardiac muscle is. For we cannot measure the muscular force of the heart itself, but only the circulatory force, and here a series of sources of error is apparent which we can not eliminate, nor even compute their relative value. And in the meantime medical selection suffers much.

But what holds good for the heart holds good equally for vascular conditions, the most important affection of which is arteriosclerosis. When we insurance physicians speak of arteriosclerosis we naturally mean the precocious, and not the senile form. From the standpoint of insurance medicine the latter can only be welcome, for we could desire nothing better than that all our insured should die of it as an accompaniment of advanced years. Arteriosclerosis becomes dangerous in insurance because it appears precociously, whether as an independent affection leading directly to death, or as an accessory cause of death when an infectious disease or any acute or chronic organic affection attacks a risk who has already become enfeebled by it. Precocious arteriosclerosis is the more dangerous because *per se* it is not a disease which reveals itself to the medical examiner by easily demonstrable symptoms.

"A man is as old as his arteries," says Cazalis, and I believe that no more just claim, none certainly which more encourages the insurance practitioner, exists than this one. Unfortunately, however, the arteries do not readily tell their age; least of all is the single examination by a physician able to reveal this guarded secret.

It happens often that only the family history can lead the medical director into the right path. For undoubtedly heredity occurs here in the sense that a definite quality of the vascular apparatus is transferred from the parents to their children. For only thus can we understand why it so often occurs that the same vascular region is involved in both parents and children. Again, these affections repeat themselves alike in the early and late periods of life, and not rarely determine the tendency to long or short life of the family.

Even in the case of tumors and their special representatives, the carcinomata, the existence has been assumed of a constitutional factor—an altered resistance of the tissues toward external irritants which prepares the soil for cancer formation. There is also the further assumption of a special exciter of cancer which settles in the pathologically altered tissues, as evidenced by the occurrence of so-called chimney sweep's cancer, smoker's cancer of the lower lip, and *x*-ray cancer. How far this theory is correct we must leave undecided. That it has so long been disregarded in life insurance is without significance because no means have been found for the recognition of the particular conditions which prepare the field for cancer. Investigations by insurance medicine of its own material have been unable to determine with any degree of certainty whether or not an element of heredity enters into cancer. The only result of the studies is to show both the increase and the enhanced malignancy of cancer in recent years. For while according to the observations of the Gotha Life Insurance Bank for the first five insurance years of the period 1881-1895 the supermortality from cancer amounted only to 12.9 per cent., the same figure for the period 1904-1908 was 40 per cent. And while in the former period only 18 per cent. of all cases occurred in the ages up to the 40th year, and 43 per cent. up to 45 in the later period, 39 per cent. occurred up to 40 years, and 61 per cent. up to 45 years; further, in this period there were no cases each in the 30th, 31st, and 32d years of life, and three cases in the 33d year. In the presence of such experiences, it is not necessary to emphasize with what great interest life insurance matches the study of cancer, and as far as possible supports it.

The Life Extension Institute.—Conceding that periodic health examinations are to form a regular part of life insurance practice, why is it not possible for each company to carry on this work separately through its own medical department? The work of examining people for the purpose of prolonging their lives is far different from that of examining applicants for life insurance. There is an entirely different psychology behind it, and the work of making these examinations effective is likewise a specialized function, which can be better performed by one central organism provided it has the equipment and the scientific backing that it should have to carry on these activities. In this way the work can be carried on in a simple manner and mistakes avoided, which otherwise each insurance company might make in the evolution of health conservation.

Mr. Harold A. Ley of Springfield, Mass., conceived the plan of forming such a central organization, and the institute was established in January, 1914.

Not only examinations for insurance health conservation, but examinations of individuals are made and also group work for factories, firms, etc. The fact should be borne in mind that these examinations of willing subjects, desirous of learning their true condition, can be made more thoroughly than a life insurance examination. The subject is stripped to his waist and the entire bodily conditions noted—eyes, ears, nose, throat, mouth, teeth, tongue, gums, etc., abdominal organs, blood pressure, systolic and diastolic, and very often the blood and sputum. The condition found, whether healthy or diseased, is reported to the insurance company which has sent the applicant and also to the individual.

Book Reviews.

OBSTETRICAL NURSING: A Manual for Nurses and Students and Practitioners of Medicine. By CHARLES SUMNER BACON, Ph.B., M.D. Professor of Obstetrics, University of Illinois and the Chicago Polyclinic; Medical Director, Chicago Lying-in Hospital and Dispensary; Attending Obstetrician, University, Chicago Polyclinic, Henrotin, German and Evangelical Deaconess Hospitals. Illustrated with 123 engravings. Price, $2.00. Philadelphia and New York: Lea & Febiger, 1915.

THIS is the latest addition to the "Nurses Textbook Series," and it is difficult to imagine a book better adapted for its purpose. The author has managed to compress into a moderate space all that the obstetrical nurse really requires. The introductory chapter dealing with the nurse's duty to herself, to the doctor, and to the patient, is full of valuable advice, and it should add to the nurse's usefulness. The author's style is exceedingly clear, and he has shown much judgment in what he has omitted. The book is of a handy size, is well printed and illustrated, and should become popular with nurses.

DISEASES OF THE BRONCHI, LUNGS, AND PLEURA. By FREDERICK T. LORD, M.D., Visiting Physician, Massachusetts General Hospital and Channing Home (for Consumptives); Instructor in Clinical Medicine, Harvard Medical School. Price, $5.00 net. Philadelphia and New York: Lea & Febiger, 1915.

THE author has endeavored to fill a present need of a practical treatise on the diseases of the respiratory organs. With a very clear idea of the exact need of the profession he has made admirable use of his obviously extensive knowledge of the literature and the tremendous amount of material supplied by the wards of the Massachusetts General Hospital. The result is an excellent and complete presentation of his subject. Pulmonary tuberculosis is not considered under a separate heading, but special attention is given to conditions which simulate pulmonary tuberculosis and their differential diagnosis. Detailed consideration is given to all pathological questions and the bacteriology, especially, is noticeably "up-to-date." Indications for surgical interference are included, as are some of the points in the surgical technique. One point, however, is deserving of severe criticism. The author has fallen into the evil habit of having his surgeon "operate a patient" instead of "operate upon a patient." This vile abuse of the English language was introduced some years ago by some of our foreign population, and seems to have found general favor, but it is disheartening to find such corruption issuing out of Boston. The work can be very highly recommended as it is undoubtedly the best on the subject in the English language.

A REFERENCE BOOK ON THE FEDERAL NARCOTIC LAW. By ALBERT DEAN CURRIER of the Chicago Bar and DANIEL R. FORBES, late with the U. S. Board of Food and Drug Inspection. Chicago, 1915.

THE new Federal Narcotic Law has brought within its scope members of the medical, dental, and veterinary professions as well as druggists, hospitals, and manufacturers who dispense, administer, or distribute what are known as habit-forming narcotics. There is still a considerable amount of ignorance concerning the interpretation of the new law, and as the penalties for the violation thereof are heavy, there is need for a brief reference book containing all the necessary information. This want has been supplied in a satisfactory manner by the issue of this short, concise reference book on the subject, which will serve as a valuable guide to those who deal in habit-forming drugs but are not acquainted with the provisions and regulations relating to the sale of the same as set down in the recent law.

A REFERENCE HANDBOOK OF THE MEDICAL SCIENCES. Embracing the Entire Range of Scientific and Practical Medicine and Allied Science. By Various Writers. Third edition, completely revised and rewritten. Edited by THOMAS LATHROP STEDMAN, A.M., M.D. Complete in eight volumes. Volume Five. Illustrated by numerous chromolithographs and 733 half-tone and wood engravings. New York: William Wood & Company, 1915.

THE subjects in this volume extend from "Head, Wounds of the," to "Life Insurance Medicine," and include some of the most important topics within the entire range of medicine. The articles on the heart, exclusive of such headings as endocarditis, arrhythmia, etc., which are dealt with elsewhere, comprise a section of sixty-one pages, and consist of separate articles on Anemic Infarction, Aneurysm, Animal Parasites, Development, Dilatation, Displacements, Fatty Degeneration, Fatty Infiltration, Functional Diagnosis and Therapeutics, Myocardial Disease, Neoplasms, Rupture, Syphilis, Thrombosis, Tuberculosis, Valvular Lesions, and Wounds of the Heart. Other large groups of articles are those on the Kidney, Larynx, Infancy, Intestines, and Jaws. Of timely interest and importance are the special articles dealing with various phases of war medicine and surgery, such as the comprehensive articles on Wounds of the Head, Military Hygiene, and Hospital Ships. The last contains a description of and a number of illustrations showing the organization of the U. S. S. *Solace*, with its chemical laboratory, *x*-ray room, dental room, etc. In addition there are given in detail the rules of The Hague Convention pertaining to maritime warfare, and the United States Army and Navy regulations governing hospital ships. The unique value of the Reference Handbook is particularly manifest in its inclusion of topics that one would not ordinarily find in other works, or that appear in this work for the first time in the reference literature of medicine. For example, one may cite the articles on Medical Examination of Immigrants, Hospital Construction and Equipment, Hospital Organization and Management, State Boards of Health, Medical Libraries, Medical Journalism, Life Insurance Medicine, etc. This volume is particularly rich in its short illustrated bibliographical sketches, including those of Hebra, Heidenhain, Helmholtz, Henle, Henoch, Hippocrates, His, Sir Jonathan Hutchinson, Edward G. Janeway, Koch, Laënnec, etc. Among the important neurological topics may be mentioned those on Hysteria, Hemiplegia, Headache, Hematomyelia, Hypnotics, and Tests of Intelligence. In the domains of biology and physiology there are lengthy articles on Inhibition, Animal Heat, Heredity, and Histological Technique. Surgery is represented by such subjects as Calculous Disease, Injuries, Tuberculosis, and Tumors of the Kidneys, Hernia, Heliotherapy, Intestinal Surgery, Artificial Hyperemia as a Therapeutic Agent, Laryngectomy, and Lateral Curvature of the Spine. There are interesting articles on Infancy and the Artificial Feeding of Infants; House Sanitation; Labor; Insect Carriers of Disease, Poisonous Insects, Intubation, Hearing and Defective Hearing, Hypertrichosis, Hypophysis Cerebri, Hemolysis, Heat Stroke, Therapeutics of Heat, Hydrotherapy and Infirmity. The Hippocratic Oath is described with reference to its history and interpretation. The illustrations are particularly numerous and include a number of full-page plates. In summing up with a brief characterization of this volume one may state that its contents are available for reading, for study, and for reference, a combination rarely achieved in medical works.

PRINCIPLES OF HYGIENE: A Practical Manual for Students, Physicians and Health Officers. By D. H. BERGEY, A.M., M.D. First Assistant, Laboratory of Hygiene, and Assistant Professor of Bacteriology, University of Pennsylvania. Fifth Edition, thoroughly revised. Price, cloth, $3.00 net. Philadelphia and London: W. B. Saunders Company, 1915.

THIS book is designed to meet the needs of students of medicine in the acquirement of a knowledge of the principles on which modern hygienic practices are based; to aid students of architecture in comprehending the sanitary requirements involved in the construction of buildings, and to aid physicians and health officers in familiarizing themselves with the advances made in hygienic practices in recent years. While the output of books on hygiene seems somewhat larger than recent additions to our knowledge warrants, in this instance the author, in his endeavor to bring his work up to date, has succeeded in presenting a very attractive and readable production. In view of the large range of topics that his subject involves no claim is made that any are treated exhaustively, but a very comprehensive general view of the subject is given. The chapters on industrial, military, and naval hygiene are particularly worthy of note. The author has been very conscientious in pointing out the unsolved problems in connection with the various topics discussed and has thus rendered a signal service in emphasizing the directions along which preventive medicine must develop. His use of the metric system throughout the book is undoubtedly commendable.

INFANT FEEDING. Its Principles and Practice. By F. L. WACHENHEIM, M.D., Attending Pediatrist Sydenham Hospital, and Mount Sinai Dispensary, New York City. Price, $2.00. Philadelphia and New York: Lea & Febiger, 1915.

A SUCCINT and clear account of the subject of infant feeding is presented in this volume. Following the opening chapters on infant digestion and metabolism, breast feeding, and cow's milk, there are described the numerous methods of milk modification. There are also chapters on other infant foods, artificial feeding, disorders of digestion, disorders of metabolism, rickets and scurvy, and the feeding of older infants. The author makes a plea for greater simplicity in artificial infant feeding, favoring the use of whole milk with the addition of cereal dilutions as originally recommended by Jacobi. He describes all the newer theories that seek to account for the alimentary disorders of infants, including the conception of salt-fever, and Finkelstein's hypothesis of milk-atrophy (Milchnährschäden). Considerable attention is devoted to the relation of infant feeding to such disorders as pyloric stenosis, pylorospasm, and digestive neuroses; to the mode of feeding in the infectious diseases; to the disorders of metabolism, including the exudative diathesis, acidosis, eczema, and urticaria; and to rickets and scurvy. The book is well written. The references to the literature and the appended bibliography are particularly helpful.

MEATLESS COOKERY. With Special Reference to Diet, Heart Disease, Blood Pressure, and Autointoxication. Compiled by MARIA MCILVAINE GILMORE. Introduction by Louis Faugères Bishop, M.D., Clinical Professor of Heart and Circulatory Disease, Fordham University. New York: E. P. Dutton and Company, 1915.

THERE is no doubt that too much meat is frequently eaten by middle aged and elderly persons, and by those who lead a sedentary life. It may be said, indeed, that too much food in general is eaten by the majority of civilized people and that individuals often "dig their graves with their teeth." After a certain age the consumption of meat should be restricted, and in some instances eschewed altogether.

The author of this work has compiled recently a book containing lists of vegetable menus, the only exception being one of chicken. The lists of diets suitable for those who cannot properly assimilate meat are excellently put together and should prove useful to this class. Dr. Louis Faugères Bishop, who is a strong advocate of rational if not always vegetable diet as a means of warding off affections of the heart and blood vessels, writes an introduction to the book in which he points out that unsuitable food has much to do with the causation of intestinal stasis, autointoxication, and the numerous physical ills that follow in their train. He advises that in order to avoid such complaints, a vegetarian diet should be followed.

MEDICAL DIAGNOSIS. By ARTHUR LATHAM, M.A., M.D. (Oxon.), F.R.C.P. (Lond.), Physician and Lecturer on Medicine, St. George's Hospital; and JAMES TORRENS, M.B., B. S. (Lond.), M.R.C.P. (Lond.); Assistant Physician, St. George's Hospital and the Paddington Green Children's Hospital. With 74 illustrations, 19 in color. New York: The Macmillan Co., 1915.

THE unique plan of this work is the concise presentation of clinical data together with laboratory methods in such manner as to provide in a form available for quick reference a broad and scientific basis for diagnosis. It combines therefore the features of the manual on clinical pathology with those of the textbook on medicine proper. A brief description of each disease is followed by a detailed description of its diagnosis, including the laboratory methods that may be employed. Then follows a full and ample discussion of differential diagnosis, each differentiated condition being given a separate paragraph. The completeness and usefulness of this phase of the work may be illustrated by the description of the differential diagnosis of typhoid fever, in which the distinguishing features of the following conditions are pointed out: septicemia and ulcerative endocarditis, miliary tuberculosis, a tuberculous storm in the mesenteric glands, appendicitis, lobar pneumonia, malaria, paratyphoid infection, and influenza. The chapter on diseases of the cardiovascular system and pericardium is particularly valuable, incorporating as it does the results of the latest studies with the aid of the polygraph and electrocardiagraph. One may question the correctness of the authors' use of the term "valvular lesions" as synonymous with "chronic endocarditis." This is a conception which has been largely discarded in favor of the newer idea that valvular lesions should be referred to in most instances as valvular defects, the result of a pre-existing pathological process. In most cases of so-called chronic endocarditis the clinical phenomena are solely the result of the mechanical defects in the heart. The topics in this book are admirably arranged from a didactic viewpoint, the illustrations are numerous, and the colored plates, including those in the section on the blood, are particularly fine. There can be no question that this book supplies a distinct want in medical literature. It bears the imprint of originality and ripe clinical experence.

THE BOOK OF PRESCRIPTIONS. With Notes on the Pharmacology and Therapeutics of the More Important Drugs, and an Index of Diseases and Remedies. By E. W. LUCAS, F.I.C., F.C.S. Pharmaceutical Chemist; Late Examiner of the Pharmaceutical Society of Great Britain; Member of the British Pharmacopœia Reference Committee; Author of "Practical Pharmacy," "The Book of Receipts." With an Introduction by ARTHUR LATHAM, M.A., M.D., F.R.C.P., Physician and Lecturer on Medicine at St. George's Hospital. Tenth Edition. Price $2.50. Philadelphia: P. Blakiston's Son & Co., 1915.

THIS little volume is intended to aid the senior student and junior practitioner in his early efforts at prescription writing. The fact that it is in its tenth edition is the best proof that the book has been of use. But the value of the work is somewhat impaired for readers on this side of the Atlantic by the fact that the preparations and doses are those of the British Pharmacopœia. The notes on Therapeutics and Pharmacology are well written and to the point.

THE NEWER PHYSIOLOGY IN SURGICAL AND GENERAL PRACTICE. By A. RENDLE SHORT, M.D., B.S., G.Sc., Lond.; F.R.C.S., Eng.; Hunterian Professor, Royal College of Surgeons; Examiner in Physiology for the F.R.C.S.; Hon. Assistant Surgeon, Bristol Royal Infirmary; Senior Demonstrator of Physiology, University of Bristol. Third edition revised and enlarged. Price, $2.25. New York: William Wood & Co., 1915.

THIS little book is of more than ordinary value. It contains such of the newer discoveries in the field of physiology as have a value in the diagnosis and treatment of patients. The author has been careful to omit mere theories and unproved statements and, with few exceptions, has given only the established and settled conclusions of many independent workers. In the present edition there will be found new chapters on the vitamines and on the genital glands; and the articles on surgical shock, the digestive apparatus, the pituitary and pineal glands, and on chloroform poisoning, have been largely rewritten. The other chapters have also been revised and brought up to date. Physicians and surgeons will find this volume a useful connecting link between the textbooks on physiology and the actual practice of medicine and surgery.

LECTURES ON THE HEART. Comprising the Herter Lecture (Baltimore), a Harvey Lecture (New York), and an Address to the Faculty of Medicine at McGill University (Montreal). By THOMAS LEWIS, M.D., F.R.C.P., D.Sc., Physician City of London Hospital, Assistant Physician and Lecturer in Cardiac Pathology, University College Hospital, London. Price, $2.00 net. New York: Paul B. Hoeber, 1915.

DR. LEWIS has made for himself a great reputation as an authority on the mechanism of the heart beat and on clinical electrocardiography. On a recent visit to this continent he gave five lectures. The Herter lectures emphasized the advantages of intimately combining clinical and laboratory observations. The Harvey lecture dealt with questions of physiological interest, while the address at Montreal served to illustrate in a more extended manner the application of laboratory methods to questions of immediate and practical consequence. The series of lectures taken together afforded an excellent exposition of the manner in which the author has cleared up, or has assisted in clearing up some moot points in connection with the action of the heart, and supplied an explanation of the method of electrocardiography. No more able exponent of the most recent views with regard to the heart, first promulgated by Mackenzie, can be found than Dr. Lewis, and the lectures contained in the book under review present these views in concise and interesting form.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held May 6, 1915.

THE PRESIDENT, DR. WALTER B. JAMES, IN THE CHAIR.

THE program of the evening was arranged by the State Department of Health.

Dr. WALTER B. JAMES, in opening the meeting, referred to the effective work which Dr. Biggs had done in New York City in reducing the death rate and making it the healthiest city in the United States. When it was observed that the death rate throughout the rural portions of the State failed to show a decrease corresponding to that of New York City, Dr. Biggs was selected as the man best fitted to prosecute a work throughout the State similar to that which he had done in New York City. The new health administration had now been in effect since January 1, 1913, during which time a Public Health Law had been enacted which was the best in this country and which had withstood all efforts to overthrow it or amend it. Though this law had been in operation but a short time the results were so striking that he felt that the members of the Academy and others would be interested in hearing of them.

The Public Health Council of the State of New York.—Dr. HERMANN M. BIGGS presented this paper. He recalled that previous to the year 1913 the powers of the State Department of Health were very restricted and almost wholly advisory in character. The Commissioner had no direct authority over the local health officers, and no power was vested in the Department to make sanitary regulations. There were about 1,400 separate health units in the State, each of which had a Board of Health and a Health Officer. Each Board of Health had the power of enacting a Sanitary Code for its own community. The cities generally of the State were an exception to this rule, and in many the City Council had the power to enact the sanitary code. To meet this condition the Commission which drafted the Public Health Law introduced the section which created a Public Health Council which should have no appointive, administrative or executive duties or powers, but should have authority to enact sanitary regulations of statewide application. Further than this, the Commission determined in the new Public Health Law to bring about the following results: First—To confer supervisory instead of advisory powers upon the Commissioner of Health and to extend the direct supervision of the Department throughout the State to the smaller communities by the division of the State into twenty sanitary districts, with a State Sanitary Supervisor in each. Second—To raise the standard of the sanitary work of the State by providing that important administrative positions should only be filled by well-trained and thoroughly qualified men, and to exclude as far as possible, the introduction of political influences in appointments in the sanitary service of the State. Third—The Public Health Law fixed a minimum compensation for local health officers of 10 cents per capita of the population of the community which each served. The Commission felt that without more adequate compensation for the local Health Officers little progress in the health administration of the State could be brought about. Fourth—There were created in the Department of Health nine divisions representing important phases of public health administration with a director in charge of each. Fifth—More complete registration of vital statistics was provided for by the incorporation in the Public Health Law of the model Vital Statistics Law, which was drafted by a joint committee of the United States Census Bureau and the American Medical Association. It was the intention of the Commission that the Public Health Council should be composed of experts representing public health administration, bacteriology, and preventive medicine, sanitary engineering, social welfare work, the medical profession and the people. The council as at present constituted included Dr. Simon Flexner, Dr. T. Mitchell Prudden, Mr. Homer Folks, Professor H. N. Ogden, dean of the faculty of engineering at Cornell; Dr. William Gaertner, Mrs. Elmer Blair, chairman of the public health committee of the State Federation of Women's Clubs, and the Commissioner of Health. The members of the council were appointed by the Governor, the term of service being six years and one expiring on January 1 of each year. After reading the sections defining the duties and powers of the Public Health Council, Dr. Biggs said it would be seen that the council was charged with three important duties: the enactment of a State-wide sanitary code which had all the form and effect of law; the establishment of qualifications for public health officials of various kinds, and to act as expert advisers on public health questions and matters of policy to the Commissioner of Health. This sanitary code replaced the fourteen hundred previously existent in the former sanitary districts of the State. It was hoped by the Commission that it would be possible to raise the standard of men in all the classes of public health work and to protect them so far as was possible from political influences. Appointments of local officials were still made by local authorities, but only such persons were eligible as had the qualifications prescribed by the council. This practically put these positions in the Civil Service class. The same provision applied to all important positions in the State Department of Health. The qualifications of directors of divisions were also prescribed. The position of Sanitary Supervisor, twenty of whom were to be appointed under the law, was placed under Civil Service rules. In the framing of the sanitary code the council had steadily aimed to secure to the citizens of the State all the advantages which science and experience had offered in the prevention of disease and in the promotion of the common welfare, with the least possible interference with the business, comfort and welfare of the people. The council had sought to eliminate from the code, especially in the chapter dealing with communicable diseases, the useless sanitary procedure which marked the views and practices of an earlier day, now replaced by exact knowledge, and to abandon in its text technical terms which had lost their earlier meanings and values and also those which were not readily comprehensible to the citizens for whose use and guidance the code was framed. Thus the council cherished the hope that the code would prove effective, comprehensible and not unnecessarily rigorous in view of the large advantage to all which the adoption and the enforcement of a modern scientific code promised. Up to the present time seven chapters of the sanitary code had been enacted. The first related to definitions and general provisions; the others to communicable diseases, milk and cream, the practice of midwives, labor camps, nuisances, the last to miscellaneous subjects, such as spitting, common drinking cup, common towel, barber shops, etc. One of the most important subjects at present engaging the attention of the council was the fixing of qualifications of local health officers hereinafter to be appointed. Owing to the existing lack of facilities or the training of health officers and to the comparative smallness of the salary, the council realized at present the impracticability of fixing at present the qualifications as high as was desirable. It was the belief of the council that the solution of this pressing problem involved the education of physicians and others in modern preventive medicine by the creation of a school of young men interested in public health, who would form a source of supply of health officers. To attract efficient young men to this important public service it was necessary to afford them attractive opportunity and adequate compensation. Those familiar with the public health law and service throughout the United States felt that for the first time in the history of this country an adequate, efficient public health law had been enacted and that a large future and useful careers had been opened to men who prepared themselves for public health work.

Certain Special Activities of the Department, Control of Midwives, Cold Storage, etc.—Dr. LINSLY R. WILLIAMS presented this communication. He stated that the various activities which he would describe were not taken up in the order of their importance. He first spoke of Public Health Nursing. He stated that the Department had an appropriation sufficient to employ eight nurses at $1,200 a year for the general public health work throughout the State. The qualifications for these nurses were that a nurse would be not less than twenty-five years of age; that she should be a registered nurse in New York State, and that she should have had not less than two years' experience after graduation in either maternity work, infant welfare, social service, tuberculosis, care of communicable diseases, or school nursing. Several of these nurses had done excellent work in connection with the infant welfare exhibits, and had been of assistance in organizing Little Mothers' Leagues. Four nurses had made quite an extensive survey in two counties in an endeavor to ascertain the amount of tuberculosis existing in those counties. Their work had initiated a cam-

paign for a new County Hospital for Tuberculosis in both counties. Another important feature of the work had been the supervision of midwives. Up to January 1, 1915, 238 midwives were licensed. Since that time the applicant had been required to possess either a diploma or show evidence that she had attended under instruction not less than fifteen cases of labor and to give the name, date and address of each case, and a written statement of the physician under whom she had received instruction. From January 1 to April 15, 1915, eighty-eight midwives had been licensed and 254 had been refused. A series of regulations controlling midwives had been enacted, modeled largely on those now in force in New York. It was the intenet of the department to instruct midwives and to attempt to improve the midwives' services, and as time went on to curtail the number of midwives and to make regulations more stringent, so that a better qualified woman would take up the work of midwifery. It did not seem practicable, and it would cause extreme hardship if the midwives were immediately abolished. Dr. Williams reviwed the law with reference to cold storage and stated that during the year 1914 there had been 5,150 inspections of cold storage warehouses and 1,845 inspections of retail stores and markets. A number of violations had been found, the majority of which were for misrepresentation, a comparatively small amount of food having been found unfit for use. Two hundred and twenty prosecutions were instituted in 1914 as against thirty-seven during the years 1911, 1912, and 1913. In reviewing the work of the division of sanitary engineering, the speaker stated that only seventy-seven water supplies in the State were protected by rules and regulations, and that there were about 400 not protected. Where violations of rules and regulations had been detected steps had been taken to abate them. Moral suasion and publicity were the only powers that the department had for correcting unsanitary conditions on these watersheds. During the past year seventy-one public nuisances arising from stream pollution were investigated by the department and eighty-one other public nuisances, all of which had been investigated and action taken in accordance with the Public Health Law. During the past seven years 1,100 summer resorts had been investigated and every effort made to see that the water supply, sewage and garbage disposal and milk supply was kept in sanitary condition. Nearly 100 State institutions had had a sanitary investigation made and report rendered thereon to the managers of the institution and to the proper State supervisory authorities. The operation of various sewage disposal plants, municipal and institutional, was also supervised. In a number of instances municipalities created public nuisances by discharging sewage into streams in violation of the law. In several instances the department had caused the State, through the Attorney-General, to bring action against a municipality. Although this law had been in force for a number of years, it had never been utilized for this purpose until this year.

Educational Work of the New York State Department of Health.—Prof. C.-E. A. WINSLOW discussed this phase of the department's activities, calling attention to the fact that it had been only within the past few years that the department had undertaken this work, and that New York was the first State to have a special division of Public Health Education as a part of the work of the State Health Department. A survey of the field showed widely varying needs in this direction. There was first the need for educating health officers. Some of the universities were acting as pioneers in this field and had established extension courses. In addition to proper education for those entering upon the public health work the State Department held an annual conference for Health Officers, the object of which was to keep these men informed and up to date on subjects relating to public health work. The conference at Saratoga Springs last fall was attended by 730 health officers. The importance of the practicing physician in public health work was recognized, and an attempt was made to reach him through the Monthly Bulletin and Health News, which was sent to every physican in the State. In addition they had distributed to physicians some twenty-two special bulletins on such subjects as communicable diseases, farm sanitation, the house fly, etc. These were distributed among volunteer workers as well as among physicians and health officers. If their work was to succeed they felt that they must reach the individual citizen and cultivate in him a sanitary conscience, and in this way they would get ahead of disease as the health officer alone could never do. After mentioning the subjects to which the Health News had devoted itself and calling special attention to the endeavor to reach the children in the public schools through a series of articles prepared for that purpose, Dr. Winslow related their experience in reaching the people through the columns of the local newspapers. They had sent short articles on health topics to 400 local papers throughout the State, and in this way had reached over a million readers. These articles had been well received by the people and the newspapers were showing a spirit of cheerful cooperation. Another branch of the public health education work was that of the lecture service. Lectures had been given to the number of about 100 monthly by the sanitary supervisors, and special lecturers and special campaigns had been undertaken through the women's clubs, labor unions, and granges. After speaking of the adult life, infant welfare and rural hygiene exhibits which had visited fifty-nine cities and fifty-three county fairs, the speaker said that they had a plan for reproducing these exhibits in a form that could be duplicated and that in this way all localities in the State could be reached. They planned to have booklets for distribution at these exhibits which would serve to impress the lessons of the exhibits in the minds of those who visited them. In preparing their literature their object had been to visualize their readers in such a way as to impress upon them the thing that they wanted them to do. A constructive plan for the future required cooperation between local organizations, through a Central Health Council in each community. In closing, the speaker again emphasized the need of individual knowledge and of organization if the people were to be effectively mobilized for public health work.

Laboratory Service for the State.—Dr. AUGUSTUS B. WADSWORTH presented this paper, in which he first briefly related the history of the laboratory of the State Department of Health. This laboratory was organized twelve years ago for the purpose of making and distributing diphtheria antitoxin. Some five years ago it began the distribution of tetanus antitoxin and about three years ago it commenced to distribute silver nitrate for the prevention of ophthalmia neonatorum. In 1906 the bacterial and chemical analysis of water was taken up. The reorganization of this work was now bringing great advantages to local health officers. A year ago last February, when the present health administration took up the work, they found the laboratories and stables, where 17 horses were kept, in a deplorably insanitary condition. It was found that in the midst of the overcrowding and chaos that prevailed the antitoxin that was prepared contained only 66 per cent. of the units it was supposed to contain. Since that time both the diphtheria and tetanus antitoxins had been standardized and were now distributed throughout the State much more generally than formerly. The tetanus antitoxin as a therapeutic remedy must be given without delay. Provisions for distribution had now been made so that telegraphic orders were seldom necessary. They were also distributing antimeningococcus serum, typhoid vaccine, and through the courtesy of the Hygienic Laboratory at Washington material for the treatment of rabies. Smallpox vaccine would soon be prepared. A new outfit had been installed for the preparation of the silver nitrate outfits for ophthalmia neonatorum. Inasmuch as the bacterial examination of water was not very satisfactory unless supplemented by a field inspection, they had succeeded in having the sanitary supervisors make such field inspections and had thus brought them in touch with the water supplies. The delay of specimens sent for diagnostic examination in transit and the deferring of examinations and reports had been a problem of concern for some months. Sometimes the delay was on the part of the physician sending the specimen and at others there was a delay on the part of the laboratory. They now telegraph the results of examinations to physicians. The result of an examination could now reach the Western part of the State in from thirty-six to forty-eight hours. They now had outfits for the diagnosis of almost every disease in which the laboratory examination was of any practical value. While their plant was still limited and no adequate appropriation or provision had been made for research work, nevertheless some had been undertaken, and offered a striking illustration of the value of research in the attainment and maintenance of a high standard of efficiency. Ninety-eight strains of diphtheria bacilli had been identified, verifying the accuracy of distinc-

tions which were now made between the pseudo and true diphtheria. Previously no such distinction was made. The different types of the agents of pneumonia were also to be studied. Other laboratories were being established throughout the State, which would cooperate with the State Laboratory, while the latter would aid in standardizing all this work. There were now 10 county and 21 municipal laboratories. In the more technical phases of the work the laboratory at Albany and the Branch Laboratory in New York would be consulted. Instruction would be given to those laboratory workers who had the prescribed requirements and to health officers. Thus had order come out of chaos. The stables had been removed outside the city and the buildings had been renovated and put into shape for laboratory work. The laboratory workers were Civil Service employees and the records of their time showed an average of 30 per cent. of overtime work that gave proof of their interest. In closing Dr. Wadsworth cited statistics showing the great increase in all departments of the laboratory service since the year 1913.

The Diminution in the Death Rate.—Dr. CRESSY L. WILBUR, Director of the Division of Vital Statistics, presented this paper in which he declared that the death rate of civilized countries during this age of modern hygiene was perhaps the most significant characteristic of our time. Formerly death rates of 40 or 50 per thousand population were not at all uncommon. Even with the high birth rates then present population did not increase as fast as at the present time. Now they were giving much practical attention to the bookkeeping of humanity, as the vital records had been termed, and undoubtedly they had at the present time a more serviceable body of data for public health purposes than ever before. An inspection of the present low death rates gave one an impression that the present rates were hardly likely to be diminished in the future to a very large extent, or at least to the extent observed in recent years. There was still, however, much opportunity for improvement. The death rate for the State of New York for the year 1914 was only 14.6 per 1,000 population. This was the lowest death rate ever recorded for the State since the establishment of accurate death records. In 1890 the rate was 20.8, so that in a quarter of a century it had declined about six points. Much more rapid had been the decrease in New York City as compared with that in the State at large. In 1900 the death rate of New York City was 20.6 per 1,000 population, and in 1914 it was only 14, a drop of six points in fourteen years. The drop was indeed somewhat more if the city estimates of population were employed. The remainder of the State showed a practically unchanged death rate in this period. There was unfortunately some little discrepancy between the published death rates for New York State and city as obtained from various sources dependent chiefly upon the various methods of estimating population for inter-censal and post-censal years. The choice of method was important, and perhaps the time had arrived for a change in the census method of estimation as the geometric method was now probably more in harmony with the observed facts of increase of population, not only for the City and State of New York, but more especially for the majority of registration states. In the census mortality statistics, 1911, the essayist had computed the specific death rates, by sex, of New York and other States, and also for the cities of 100,000 population and over, according to eleven age periods with a view to the statement of a corrected or standardized rate. Similar figures were presented for the State in 1900, so that the movement of mortality at the various age periods, by sex, could be compared for the eleven-year interval. Similar tables were presented in the Special Report of Professor Wilcox in the Annual Report of 1912, the figures relating to the census years 1900 and 1910. His conclusion which was in close agreement with that of the speaker was that a falling death rate was found among men below 45 and among women below 60 years of age. The death rate of males seemed to follow, by an interval of several years, the path of possibility blazed by the female rate. In other words, by greater protection from life hazards, by greater moderation of restraint and perhaps greater adaptability to the increasingly feminized conditions of modern life, woman was the healthier animal, and as fittest, was surviving to a greater extent at practically every age. Life tables would soon be available for the registration area of the United States and for individual states, by means of which exact comparisons could be made as to the relative mortality and life expectancy at each age. The speaker showed such a comparison between the New York City life table and those recently published by the Registrar General for England and Wales and the County of London. These tables showed that the life expectation was greater at practically all ages in England and Wales than in New York City. In discussing the question as to what could be anticipated for the future in the way of reduction of the general mortality, Dr. Wilbur said he believed the death rate of both New York City and New York State would continue to decrease for a period of some years. A death rate of 10 per 1,000 in a stationary population would represent an average longevity of 100 years. But our populations were growing, both by natural increase and by immigration, and hence they had by no means reached the lower limits of the general death rate under these conditions. Their great problem was the reduction of the death rate outside the City of New York, and especially in the smaller cities, villages and towns of the State. A difficulty in this connection was the fact that the age distribution of the rural communities was less favorable on account of the larger proportion of persons at advanced ages.

The New York State Department of Health and Infant-Welfare Work.—Dr. HENRY L. K. SHAW of Albany reviewed this division of the work. He declared that New York State could point with pride to the fact that it was the first state in the union to officially recognize the claim of the child through the formation in the State Department of Health of a special division devoted to his interests. No resources of the state were in such dire need of conservation as its children. After briefly reviewing the results of infant welfare work in New York City, Dr. Shaw stated that the infant mortality statistics in 1913, outside of the City of New York, showed that the infant date rate was 126 per 1,000 living births in comparison with 102 in New York City, where infant welfare work was in operation. Dr. Biggs then insisted that a special effort be made to reduce this high infant mortality and inaugurated through the Division of Child Hygiene a state-wide campaign to accomplish the result. The objects of the campaign were to educate the mothers in the care of their children and to arouse the community to the necessity for child welfare work, to point out the fact that a high infant death rate was unnecessary and should be considered a disgrace, to establish infant welfare centers with the employment of visiting nurses and to improve the general milk supply. Three exhibits were prepared which consisted of 20 large panels and a fully equipped infant welfare station. These exhibits started the first of April and continued until the first of July, when 45 cities and large villages had been visited and over 150 public meetings held. Advance publicity work was started in each city about two weeks before the coming of the exhibit. The trained nurse who had charge of the model infant welfare station weighed babies, gave advice to mothers and held informal talks on the bathing and care of the baby whenever a group was collected. A bed prepared for a maternity patient was included in the equipment and the steps in its preparation were demonstrated by the nurse in charge, who presented a leaflet entitled "Before the Baby Comes," and advised expectant mothers to consult a physician early and to take special care of their diet and clothing during the prenatal period. The results of the campaign were that 35 new stations were established in 22 new localities. In 18 of the 45 cities the infant mortality rate fell below 100 per thousand living births and in 31 of the cities the death rate fell below that of 1913, while in 12 cities not reached by the exhibit, in only four did the death rate fall below that of 1913. The infant mortality rate for the entire State was 101, which was per thousand living births in 1913 to 111 in 1914. When the rate for New York City was included, the infant mortality rate for the entire State was 101, which was lower than any State in the Union. Besides visiting 45 cities, the exhibits were sent to 57 county fairs. The State Department was continuing this work in rural communities. It was difficult, sometimes almost impossible, to educate the mother of the baby, but it was possible to reach the big sister through the public school. If the girls who would be the mother of the next generation could be taught how to take proper care of infants they might hope to diminish not only the high death rate among infants, but also the vast amount of unnecessary ill health and physical suffering

caused by neglect in infancy and childhood. The plans of the Division of Child Hygiene for the coming year were to conduct a campaign of education in localities which were not reached last year, and to establish more infant welfare stations. Efforts would be made to reduce the mortality of the first months of life by prenatal care and instruction. A study of the causes producing high infant mortality in infants' institutions would be undertaken and an effort made to reduce the number of deaths from respiratory diseases.

The Treatment of Diphtheria Carriers.—Dr. F. M. MEADER, Director of the Division of Communicable Diseases, read this paper. After considering the anatomical and pathological changes that took place in the parts usually involved in an attack of diphtheria, he stated that in diphtheria carriers these pathological changes in the epithelium might be observed long after the clinical manifestations of the disease had disappeared. On the tonsils, even in normal appearing tonsils, the local foci might be found studded over the surface. These foci were not apparent to the unaided eye. Whether or not these foci were as numerous on other parts of the mucous membrane as on the tonsils was not known. The fact that Overton, Zingher and Turrell had obtained negative reports from cultures in 16 of 18 carriers immediately after tonsillectomy might lead one to infer that the foci were confined chiefly to the surface of the tonsil, but they had no information regarding other surfaces since they might not have been touched by the swab. It had been observed that when the mucous membrane was unhealthy it might become secondarily infected with diphtheria bacilli. For example, a foreign body as a shoe button in the nostril had repeatedly been known to irritate the mucous membrane in such a way that a secondary infection with diphtheria bacilli had persisted for months with no clinical symptoms. When the button was discovered and removed the diphtheria organisms disappeared. It had been observed that when the mucous membrane had been infected with tuberculosis or syphilis, if a secondary infection with diphtheria germs occurred, it had been impossible so far as he knew to affect the carrier state until the primary lesion had disappeared. It would thus seem that at least a factor in the carrier state might be some primary pathological condition of the mucous membrane. Another interesting observation of these carriers was that they possessed natural antitoxin. In the treatment of these cases the removal of the primary condition was of importance. In the medication care must be exercised lest the caustic applied did not so injure the mucous membrane that a vicious circle was produced. Frequent spraying with a simple normal saline sufficient to keep the parts clean, the idea being to stimulate the production of a normal mucous membrane, had been used with success, but this method was tedious and sometimes of long duration. The spraying of the mucous membrane with a living culture of staphylococcus aureus, or lactic acid bacillus, or bulgarian bacillus had often been tried and reported as successful. In their hands it had been easy to obtain negative cultures for a few days following the use of such a method, but subsequently the diphtheria organisms were found to persist. They felt that the diphtheria organisms were simply overgrown in these cases. The immunization of carriers with autogenous vaccines made from the diphtheria bacillus had received some attention. In the literature and in his personal experience, it appeared that if the usual technique for demonstrating bacteriolytic amboceptors in the blood was employed none of these antibodies could be found. However a slight modification in the technique made it possible to demonstrate an amboceptor-like body, which was produced by immunization with the diphtheria bacilli. This antibody disappeared soon after immunization ceased. The frequent examination of the blood of patients convalescent from clinical diphtheria who recovered normally failed to show any trace of this antibody, so that they did not feel that immunization with diphtheria vaccines, at least with methods used, was a fruitful field of endeavor. Removal of the tonsils of diphtheria carriers was usually followed immediately by the report of negative cultures. There was no report of serious complications following this procedure. But there was no data to show that foci on a large part of the mucous membrane might not still be infected. In discussing the danger of the carrier to the community, Dr. Meader stated that it had been estimated that about 0.4 per cent. of the general population were carriers. During epidemics the percentage rapidly increased. Since last August it had been the rule of the Department to release from quarantine patients whose nose and throat had been normal for five weeks. There were three conditions stipulated: 1. The patient must be careful about coughing or sneezing in the presence of little children. 2. Cultures must be taken at intervals of two weeks until the diphtheria bacilli disappeared. 3. There must be an agreement that any secondary cases traced to such carriers be immediately reported to the Department.

Dr. WILLIAM HALLOCK PARK said that Dr. Meader's experiments brought back a recollection of some work that he had done some years ago which led him to the conclusion that in dealing with carriers a simple method of cleansing was the best. In their investigations they had found that carriers were more frequent than had been supposed. About 10 per cent. of children with scarlet fever were carriers as against one per cent. of ordinary children. There must be some condition of the naso-pharynx in scarlet fever that made it a suitable nidu for the bacilli. The speaker said he could scarcely concur in the belief that after a certain length of time, and on one negative examination, a carrier was no longer a menace. That was only true of carriers who had had the disease. It seemed unreasonable to allow a carrier, even if time had elapsed and one examination had been shown to be negative, to enter a community where no diphtheria and no such carrier existed. Dr. Wadsworth had spoken of educating public health officers along public health lines. The majority of medical schools now offered an extension course or had added a course in this subject to their curriculum, and he hoped that the Council would add this requirement as a qualification for public health work. Learning from the State Health Department seemed new to them, but he believed this was the beginning of cooperation between the city and the state, and that each would get information from the other, and there would spring up between them a spirit of generous rivalry that would be of benefit to both.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

STATE BOARD OF MEDICAL EXAMINERS OF GEORGIA.

Atlanta, October, 1914.

(*Continued from page* 46.)

OBSTETRICS.

1. What are the characteristics of the female pelvis and how does the male pelvis differ therefrom?
2. Describe pelvimetry and name the five most important measurements.
3. What precaution as to the urine should be employed in the case of a pregnant woman.
4. Describe methods to determine position of the fetus previous to labor.
5. Define second stage of labor and state the conditions which may cause delay of delivery in this stage, and how such conditions should be managed.
6. How would you determine that a dead infant had been born alive?
7. Give the technique of obstetric asepsis and antisepsis before, during and after labor.
8. Give your method of caring for the new born from birth until it is dressed. (*b*) What attention should the babe's eyes receive?
9. Give causes, symptoms,, and treatment of phlegmasia alba dolens.
10. Discuss gonorrhea in women—symptoms and far-reaching results.

DISEASES OF WOMEN.

1. Describe the uterus.
2. Define menorrhagia; (*a*) Give causes; (*b*) treatment.
3. What is the usual cause of menorrhagia in virgins?
4. Define chronic simple endometritis. (*a*) Give some of its synonyms; (*b*) causes and treatment.
5. Give symptoms and treatment of urethral caruncle.
6. What is the main support of uterus?
7. What is the main object in repairing the perineum?
8. Describe an operation for the repair of perineum.

9. Define pyosalpinx and give your method of handling same.

10. Diagnose cancer of uterus.

ANSWERS.

OBSTETRICS.

1. The chief differences between the male and female pelvis are thus tabulated in Morris's *Anatomy:*

MALE.	FEMALE.
Bones heavier and rougher.	Bones more slender.
Ilia less vertical.	Ilia more vertical.
Iliac fossæ deeper.	Iliac fossæ shallower.
False pelvis relatively wider.	False pelvis relatively narrower.
True pelvis deeper.	True pelvis shallower.
True pelvis narrower.	True pelvis wider.
Inlet more heart-shaped.	Inlet more oval.
Symphysis deeper.	Symphysis shallower.
Tuberosities of ischia inflexed.	Tuberosities of ischia everted.
Pubic arch narrower and more pointed.	Pubic arch wider and more rounded.
Margins of ischiopubic rami more everted.	Margins of ischiopubic rami less everted.
Obturator foramen oval.	Obturator foramen triangular.
Sacrum narrower and more curved.	Sacrum wider and less curved.
Capacity of true pelvis less.	Capacity of true pelvis greater.

2. *External pelvimetry.*—"The measurements are made with a pair of calipers. *Interspinous diameter.*—The points of the calipers are held in the two hands so that the point of the forefinger rests alongside the point of the instrument. The two anterior superior spines are located, and the points placed on them. The calipers are then screwed tight by an assistant or nurse, and the measurement read off. Normally it is 9½ to 10 inches. *Intercristal diameter.*—The instrument is held as before and the points passed slowly round the iliac crests until the points of greatest separation are found, when the measurement is made. Normally it is 10½ to 11 inches. The *external conjugate diameter* is measured by placing the one point of the calipers over the tip of the last lumbar spine, and the other over the front of the symphysis pubis. This is most easily done with the patient standing, and the tip of the last lumbar spine can be found by counting downwards from above. It is, however, usually marked by a slight dimple due to fascial attachments. In fat persons it suffices to make a point in the mid line 2½ inches above the line joining the posterior superior iliac spines. The external conjugate usually measures about 7½ to 8 inches; 3½ inches at the very least must be allowed for the thickness of the bony and soft tissues. Therefore, while a large reading may not necessarily mean a large conjugate, a reading under 7½ inches, and more especially under 7 inches, indicates that the conjugate is diminished proportionately.

"*Internal pelvimetry.*—The *diagonal conjugate* from the promontory of the sacrum to the under margin of the symphysis may be measured by the fingers. The diagonal conjugate measures 4½ to 4¾ inches, and ½ to ¾ of an inch must be subtracted to give the length of the conjugata vera. The actual amount to be subtracted varies with the depth of the pubic bone and its inclination toward the sacrum, so that at the best this method of estimation is but approximately correct. In practice, however, these methods are found to be sufficiently accurate in the vast majority of cases. It should be remembered that in a normal pelvis it is impossible to touch the promontory of the sacrum by vaginal examination without forcing the fingers so far in as to hurt the patient. Therefore if the promontory can be felt readily it indicates a small pelvis and the desirability of more careful investigation. The *outlet of the pelvis* can be directly measured in both its anteroposterior and transverse diameters by means of the fingers and a measuring tape, or more conveniently by means of a pair of calipers with the points crossed."—(Johnstone's *Textbook of Midwifery.*)

3. "The *urine* should be examined at regular intervals throughout pregnancy. This examination should be both chemical and microscopical, and made at least once a month for the first six months, and once a week during the last four. The presence of albuminuria, the evidences of toxemia, edema, renal insufficiency, or nephritis, demand daily examinations. This examination should determine the amount of urine passed in twenty-four hours, its specific gravity, the total amount of urinary solids, the percentage of urea, the presence or absence of albumin or sugar and of tube casts."—(Polak's *Manual of Obstetrics.*)

4. *Methods of determining the position of the fetus prior to labor:*—"The examiner stands alongside the patient, facing her head; the tips of the fingers of both hands, moving together and at equal distances from the middle line, are carried up the sides of the abdomen by a series of tapping movements; and upon one side (for example, the left, in the L. O. A. position) is noticed a firm, broad, even sense of resistance, contrasting with the cystic, tumor-like sensation of the other side, with the occasional encounter of firm, irregular bodies,—the fetal extremities. This firm, broad, even resistance is produced by the fetal back, and, to confirm this fact, the extremities are felt for by a rubbing motion with one outstretched hand on the opposite side. They are felt as cylindrical, irregular bodies, slipping away from the hand, and changing their position from time to time. Having located the back and the extremities, the portion of the fetal ellipse presenting at the superior strait is next ascertained. The examiner now faces the woman's feet, and, with the outstretched hands, the fingers parallel with and the middle finger over the center of Poupart's ligament, on either side, the fingers dip down beneath the ligament into the pelvic cavity. If the head is presenting, it is felt as a hard, regular, round body, the greater mass of the occiput, the sharp point of the chin, and the groove between occiput and back being often distinguishable. At the same time, the density of the head, its compressibility, its approximate size, and its relative size to the pelvis may be learned. By *auscultation* the fetal heart-sounds are located, and their rate and intensity are noted. The uterine bruit and the funic souffle are often heard. The former is a low-pitched musical murmur synchronous with the maternal heart-beat. The latter is a high-pitched whistling murmur synchronous with the fetal heart-beat. The position of the abdomen at which the fetal heart-sounds are heard with greatest intensity is of diagnostic value in confirming the find, by abdominal palpation, as to position and presentation. By *vaginal examination* the finger detects the varying portions of the fetal body which may present at the superior strait, as the cranium, the face, the shoulder, the buttocks, the knees, feet, and, exceptionally, the elbow or hand."—(Hirst's *Obstetrics.*)

5. The second stage of labor begins when the os is fully dilated, and terminates with the expulsion of the child. Conditions which may cause delay are rigidity, edema, atresia, or displacement of the os or cervix; fibrous bands or atresia of vagina; persistent hymen; unyielding perineum; tumors; distended bladder or rectum; hernia; edema of labia; pelvic deformities; malpositions or malpresentations of the fetus; prolapse of limbs; short cord; large fetus; dead fetus; twins or monstrosities; uterine inertia; rupture of uterus.

It is manifestly impossible, in the space at our disposal, to give the treatment of all these conditions.

6. *Application of hydrostatic test, to determine whether a dead infant was born alive:*—"Having opened chest, note *position* of lungs (*before* respiration they occupy a small space at upper and posterior parts of thorax); their *volume* (of course increased after breathing); their *shape* (before respiration, borders sharp or pointed; after it, rounded); their *color* (before breathing, brownish-red; after it, pale red or pink); their *appearance* as regards disease and putrefaction; and whether they *crepitate* on pressure (as they will *after* respiration). Take out lungs with heart attached, and place them in pure water having temperature of surrounding air. Note whether they float (high or low), or sink (slowly or rapidly). Separate them from the heart and weigh them accurately; then place them in water again, and note sinking or floating, as before. Subject each lung to pressure with the hand, and note sinking or floating again. Cut each lung in pieces and test floating again. Take out each piece, wrap it in a cloth, and compress with fingers as hard as possible, and test floating, etc., as before. The crucial test of *perfect respiration* is each piece floating after the most vigorous compression." (King's *Manual of Obstetrics.*)

7. In addition to the bath, clean clothes, and other details which may be taken for granted in persons of refinement, the physician should, before making a vaginal examination, carefully cleanse his hands, as

scrupulously as if he were about to undertake a major operation. The hands should be scrubbed for at least five minutes with hot water, soap, lysol, and a nail brush that has been boiled or soaked for some time in an antiseptic. Special care must be given to the nails and nail-folds. The hands should then be soaked for three minutes in an antiseptic solution such as bichloride of mercury 1:1000. This is followed by another washing in sterile water. Rubber gloves that have been boiled and kept sterile and a sterile gown add to the safety of the patient.

The patient should receive a full bath before labor begins and all bed-clothing and personal clothing should be clean. If there are any pathological discharges from the genitals, the vagina should be thoroughly scrubbed with tincture of green soap and hot water, followed by a mercuric chloride douche (1:2000); this followed by a douche of sterile water. The physician's hands should be scrubbed for ten minutes with tincture of green soap and hot water, followed by alcohol, and immersion in mercuric chloride (1:100). All instruments should be boiled for ten minutes or immersed in mercuric chloride 1:1000 for half an hour. Examinations should be made when necessary to determine the position, presentation, size of the fetus, etc.

8. *Care of infant:* After the cord has been ligated and cut, the eyes should be cleansed with a saturated solution of boric acid, after which, if there is any vaginal discharge from the mother, 1 or 2 drops of a 1 per cent. solution of silver nitrate should be instilled in each eye. The mouth should also be gently cleansed, for which may be used a soft cloth and boiled water. The vernix caseosa should be removed by means of some oily substance. The baby should be bathed in water at 100° F., carefully dried, and the cord dusted with some antiseptic powder. Sponging should be practised for 10 days, after which a full tub-bath at 98° F. should be given daily for 6 months. The temperature may then be reduced to 95° F., and at the end of a year to 90° F. The binder and clothing should be woolen. If the infant's extremities are blue or cold, external heat should be applied. The diapers should be made of flannel, and dusting powders should be used to prevent chafing."—(*Pocket Cyclopedia.*)

Ophthalmia neonatorum is an infectious, purulent inflammation of the conjunctiva in the newborn, due to the gonococcus or other pyogenic germ; produced by contact of the eye with the vaginal secretion of the mother during labor, or infected fingers, or instruments, etc. *The treatment is* (1) *Prophylactic.*—Whenever there is the possibility of infection, or in every case, wash the eyelids of the newborn child with clean warm water, and drop on the cornea of each eye one drop of a 1 or 2 per cent. solution of nitrate of silver, immediately after birth. (2) *Remedial.*—Wash the eyes carefully every half hour with a saturated solution of boric acid; pus must not be allowed to accumulate. Two drops of a 2 per cent. solution of nitrate of silver must also be dropped on to the cornea every night and morning. The eyes must be covered with a light, cold, wet compress. The patient must be isolated, and all cloths and compresses used must be burned.

9. PHLEGMASIA ALBA DOLENS is a form of manifestation of puerperal sepsis in which there is a thrombosis of the iliac or femoral vein. Sometimes it occurs after a uterine phlebitis, in which clots are carried from the uterine sinuses to the hypogastric veins, where they cause obstruction to the blood flow in the crural veins. The trouble may also begin as a crural phlebitis. It is thus due either to cellulitis or to thrombosis. It usually appears about the third or fourth week of the puerperium. *Symptoms:* Irregular chilliness and malaise, pain in leg and abdomen, rigor and swelling of leg, fever, skin is white and tense, and the vein feels hard. *Treatment:* Rest in bed, support patient's strength, relieve pain, and apply lead and opium wash to take down the inflammation.

10. GONORRHEA. *Symptoms:* Pain and burning in the vulva; pain and burning on micturition; dyspareunia; yellowish or greenish discharge, in which the gonococcus can be found; the vagina is hot, red, swollen, and tender. *Possible results:* Cystitis, urethritis, vulvitis, endometritis, salpingitis, septic peritonitis, sterility, condylomata of vulva, abscess of Bartholin's glands. *Diagnosis* is made from the symptoms, particularly from finding the gonococcus in the discharge. It is *so serious*, on account of the possible results, enumerated above; it often leads to chronic invalidism, and may be the cause of death.

Treatment: Rest, if possible in bed; freedom from alcoholic or sexual excitement; a mild and unirritating diet; salines and diuretics; plenty of water to drink; a warm sitz bath; douching of vagina with about a gallon of a 1:5000 bichloride solution, or of borax (1 dram to the quart), or of potassium permanganate (1 per cent. solution); the douche is to be taken in the recumbent position.

DISEASES OF WOMEN.

1. In the nulliparous adult the uterus is about three inches long, about two inches wide at the upper part, and about one inch thick. The uterus lies between the rectum behind and the bladder in front; it is below the abdominal cavity, and above the vagina. Its position is one of slight anteflexion, with its long axis at right angles to the long axis of the vagina. The anterior surface of its body rests on the bladder, and the cervix points backward toward the coccyx. The uterus is not fixed, but moves freely within certain limits. It is held in place by ligaments. (1) *Broad ligaments*, which extend outward on each side from the side of the uterus to the side of pelvis. (2) *Rectouterine ligaments*, which extend backward from the intraperitoneal portion of the cervix uteri to the peritoneal investment of the rectum. (3) *Round ligaments*, which extend from the uterus just below the Fallopian tubes, through the inguinal canal to the labia majora. (4) The *ovarian ligaments*, which extend from the superior part of the uterus, behind the Fallopian tubes, to the inner end of the ovary. (5) The *uterosacral ligaments*, which extend from the highest part of the cervix uteri to the sides of the sacrum opposite the lower border of the sacroiliac synchondrosis.

2. *Menorrhagia* is an excessive loss of blood at the menstrual periods. *Local causes:* Uterine displacements, malignant disease, inflammations of uterus or appendages, fibroids, cystic degeneration of the cervix, subinvolution, ectopic gestation, abdominal tumors.

General causes: Hemophilia, scurvy, purpura, malaria, anemia, mitral disease, diseases of kidneys, or liver, acute infectious fevers.

Treatment: Remove the cause, if possible; treat abnormal conditions that are present; vaginal douches, tampons, and curettage have been recommended; also ergot, hamamelis, hydrastis, and viburnum prunifolium; rest in bed is necessary. Intrauterine applications of astringents or of adrenalin have been used.

3. *The usual cause of menorrhagia in virgins* is some general systemic condition; but uterine congestion, polypi and fibroids must not be forgotten.

4. *Chronic endometritis* is a chronic inflammation of the mucosa lining the uterus. *Causes:* Debility, repeated pregnancies, laceration, and subinvolution of uterus, fibroids, gonorrhea, or sepsis. *Symptoms:* Neuralgic, bearing-down pains; cramps; dysmenorrhea; irritable bladder; menorrhagia or metrorrhagia; leucorrhea, which may be blood-stained or purulent; profuse hydrorrhea; loss of appetite, constipation, dyspnea, palpitation, sterility. The uterus as a whole is abnormally tender; the uterine cavity is enlarged; the external os is patulous, and shows a tendency to bleed on being touched. *Treatment:* The general health must be attended to; rest is indicated; constipation must be avoided; tonics are of slight use; ergot is useful for the menorrhagia or metrorrhagia; vaginal douche, pessaries, hip-baths, and counterirritation have all been recommended; curettage may help; and one or both lips of the cervix may be amputated.

5. *Urethral caruncle* is a small red fleshy growth generally situated on the posterior part of the meatus of the urethra. There are local pain and tenderness, which may be excessive; a burning sensation is experienced on urination; it may bleed. The proper treatment is to excise it or destroy it with the thermocautery.

6. The main support of the uterus is the perineum, chiefly the sling of muscles and fascia which surrounds the vagina and its opening.

7. The *main object in repairing the perineum* is to prevent atrophy of the injured muscles, subinvolution and prolapse of the uterus.

8. *Operation for lacerated perineum:* "The labia are seized with Allis' forceps at the level of the lowest carunculæ myrtiformes. A guide stitch is placed in the posterior vaginal wall directly under the external urinary meatus. By pulling one Allis forceps and the guide stitch in opposite directions outward and downward, the posterior sulcus is exposed; denudation is required, even in a recent tear, for a part of it is always submucous. The other sulcus is exposed and de-

nuded. Then by holding the guide stitch upward in the middle line and pulling the forceps apart the mucous membrane between the sulci is denuded or freshly torn surfaces covered with granulation-tissue are scraped with the edge of a knife. The ruptured levator ani muscle in the posterior sulci is united with a double tier suture of chromic gut, two half hitches being taken in the stitch as it turns upward after coming down from the apex of the wound, in its deeper portion to the base. One knot at the apex of the sulcal denudation secures the stitch. The retracted ends of the transverse perinei and bulbocavernosus muscles are brought together by silkworm sutures. Finally, a single stitch at the top of the perineal wound unites the posterior commissure of the vulva, restoring the fossa navicularis. The perineal stitches are knotted; they are removed on the twelfth day."—(Hirst's *Obstetrics.*)

9. *Pyosalpinx* is a condition in which the Fallopian tube is distended with pus as the result of a salpingitis which has become purulent. The *treatment* of the acute form consists in rest in bed, free purgation with Rochelle salts (5i every hour), hot vaginal douches, and hot applications to the abdomen. If the symptoms become more severe celiotomy is indicated. The chronic form may be treated during the menstrual period by rest in bed, free purgation, hot vaginal douches, local applications of iodine to the cervix and vaginal vaults, and glycerin tampons. If these measures fail removal of the tube and ovary and replacing the retroverted uterus, etc., are necessary.

10. *Cancer of the body of the uterus is diagnosed* by the history, symptoms, physical signs, and microscopic examination. It is a disease of advancing years, and generally occurs after the menopause; nulliparæ and multiparæ are equally liable. The chief symptoms are hemorrhage and discharge with an offensive odor, pain, and cachexia. The cervix is soft, the uterus enlarged, and tender. The uterus must be curetted, and the scrapings examined by the microscope.

(To be continued.)

BULLETIN OF APPROACHING EXAMINATIONS

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION†	
Alabama*	W. H. Sanders, Montgomery	Montgomery	
Arizona*	J. W. Thomas, Phoenix	Phoenix	
Arkansas	W. S. Stewart, Pine Bluff	Little Rock	
California	C. B. Pinkham, Sacramento	Los Angeles	Dec. 14
Colorado	David A. Strickler, Empire Building, Denver	Denver	
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	
Delaware	J. H. Wilson, Dover	Dover	
Dist. of Col'bia	E. P. Copeland, Washington	Washington	Oct 12
Florida*	E. W. Warren, Palatka	Jacksonville	Dec. 7
Georgia	C. T. Nolan, Marietta	Atlanta	
Idaho*	J. F. Schmershall, Jerome	Wallace	Oct. 5
Illinois	C. S. Drake, Springfield	Chicago	
Indiana	W. T. Gott, Crawfordsville	Indianapolis	
Iowa	G. H. Sumner, Des Moines	Des Moines	
Kansas	H. A. Dykes, Lebanon	Topeka	Oct. 12
Kentucky	J. N. McCormack, Bowling Green	Louisville	
Louisiana	E. L. Leckert, New Orleans	New Orleans	
Maine	F. W. Searle, Portland	Portland	Nov 9
Maryland	J. McP. Scott, Hagerstown	Baltimore	Dec. 14
Massachusetts*	W. P. Bowers, State House, Boston	Boston	
Michigan	B. D. Harison, 205 Whitney Building, Detroit	Lansing	Oct. 12
Minnesota	T. McDavitt, St. Paul	Minneapolis	
Mississippi	F. H. Galloway, Jackson	Jackson	Oct 5
Missouri	J. A. B. Adcock, Jefferson City	Kansas City	Sept. 28
Montana*	Wm. C. Riddell, Helena	Helena	Oct. 5
Nebraska	H. B. Cummins, Seward	Lincoln	
Nevada	S. I. Lee, Carson City	Carson City	Nov. 1
N. Hampshire	Walter T. Crosby, Manchester	Concord	
New Jersey	H. G. Norton, Trenton	Trenton	
New Mexico	W. E. Kaser, East Las Vegas	Santa Fe

Wisconsin	J. M. Dodd, Ashland	Madison	Jan 11
Wyoming	H. E. McCollum, Laramie		

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for all the details regarding the examination in any particular State.

Therapeutic Hints.

Preparations of Cinchona Suitable for Chronic Paludism.—Gilbert states that these may be given in the form of a wine, a syrup, an infusion, or a pill. The wine may be prepared as follows:

℞ Cinchona rubia, 25 grams.
Alcohol (60 per cent.), 75 grams.
Dilute hydrochloric acid, 2 grams.
Red wine, 920 grams.

Of this 50 to 100 grams may be taken daily after meals.

The following is the formula for the syrup:

℞ Cinchona rubra, crushed, 100 grams.
Alcohol (30 per cent.), 10 grams.
Sugar, 1,000 grams.
Distilled water, q. s. ad 1,525 grams.

The dose is the same as that of the wine. The infusion is prepared with 20 grams of cinchona bark in one liter of water for 20 hours. It may be drunk freely, preferably after meals.

Pills, consisting of 0.2 gram of cinchona, may be administered to the extent of 5 per diem, during meals, and increased gradually to a daily dosage of 10 pills.—*Journal des Praticiens.*

Magnesium Sulphate in Acute Rheumatism.—Thiroloix and Mairesse extol the value of intramuscular injections of a 25 per cent. aqueous solution of magnesium sulphate in doses of 4 cubic centimeters daily. This method of treatment not only relieves the pain but also lessens the fever and shortens the course of the rheumatic attack. The magnesium sulphate may be given alone or in conjunction with sodium salicylate. Generally four injections suffice to effect a cure.—*Bulletin Général de Thérapeutique.*

Antiseptic Iodine Solution.—Dr. H. W. Yeamans, first lieutenant, Medical Reserve Corps, U. S. A., says he has used the following formula to the exclusion of all others during the past eight years, with better results and greater satisfaction than any other disinfectant has ever given him:

℞ Iodine, 1.00.
Potassium iodide, 2.00.
Salicylic acid, 5.00.
Alcohol (70 per cent), 100.00.

Undiluted, this solution may be made use of for sterilizing the hands and sites of operation; for disinfecting wounds, and for such other purposes as will readily suggest themselves. For wet dressings and for irrigations it should be diluted with water so as to represent an iodine content of from 1:1000 to 1:5000; diluted to 1:25,000, it may be used for eye (gonorrheal ophthalmia) and urethral irrigations, with excellent results, though it is advisable to cocainize the eye previously. The solution is not deleterious to instruments; in fact, it may be used for sterilizing them, other means failing.—*The Military Surgeon.*

Strychnine, Iodine, and Arsenic in Typhoid Fever.—Vernier believes that this combination of drugs exerts a specific influence in typhoid fever. The strychnine is given in daily doses of 2 to 4 milligrams. The iodine and arsenic are administered together as follows:

℞ Solution of potassium arsenite (1 per cent), 1.5 grams.
Potassium iodide, 0.50 gram.
Tincture of iodine (10 per cent), 15 grams.

M. et Sig.: Six to 8 drops in milk every 3 hours, or 12 to 16 drops every 6 hours.—*Journal de Médecine et de Chirurgie Pratiques.*

ANGINA PECTORIS.*

By RICHARD STEIN, M.D.,

NEW YORK.

VISITING PHYSICIAN TO THE GERMAN AND THE LEBANON HOSPITALS.

If one will read with care the description of angina pectoris as it was set down by William Heberden[1] nearly a hundred and fifty years ago, the physician who gave the complaint the name it bears, one will find in the three short pages of his commentaries and in the letter of Edward Jenner which was addressed to Heberden concerning the case of their mutual friend, John Hunter, if not the sum of our present knowledge of the subject approximately the substance of what we know of the nature of this "sphynx of diseases."

In Heberden's account we read: "It is different from other chest pains, or, as we might say, it is an affection *sui generis*." It is not extremely rare, the author states—he had seen a hundred cases. The experience of the busy practitioners of today is probably equally as large, especially if we include the rudimentary syndromes observed in the course of heart disease at the time of decompensation. Heberden's cases were mostly in men beyond the age of fifty, the period which we recognize as that of arteriosclerosis of the vascular system. Heberden saw the pain set in after exertion or after a meal; he saw it recede or vanish when the patient was at rest. All of this is now generally interpreted by saying that rise of the blood-pressure may bring on an attack. Heberden continues: "There is a sense of strangling or anxiety over the sternum, and down the left arm, rarely the right, sometimes in the hand and fingers." Patients have described this to me as a feeling of constriction around the chest to the point of extinction—to the very imminence of death. Heberden adds: "There are cases which end fatally that never show any but the pains in arms and hand." Osler speaks of such cases as extrapectoral angina in contradistinction to those with intrapectoral pang. The pain is, in fact, different from other chest pains, different from the sharp sore pain of pleurisy. It is a dull or deep boring pain under the chest bone, spreading to one or both shoulders, down to the arms and fingers, left or right, or into the neck, jaws, or teeth, or to the back of the head. Or it may begin in the abdomen like a true colic, and combine itself with the chest pain. Or it may shoot into the back or testicle. Very common are stationary pains on trunk, arms, and wrist. In fact, long experience has taught us many localizations, combinations, and variations. Nothing is easier than to miss the significance of atypical anginal pain or to misinterpret certain gastric symptoms. Often they are the unrecognized warning-signal of death. Pain in the fingers of the left hand is characteristic. Popularly the left ring-finger is thought to have a special relationship to the heart. Heberden also describes, though in not so many words, what is known as the chronic state of angina, the status anginosus.

The pulse is at least sometimes not disturbed by this pain, he says. This is also our experience. The prognosis in the progressive cases is given by the author in one short phrase: If no accident supervenes, the patients all suddenly fall down and perish almost immediately. This tragic ending, oftentimes so unexpected, has been the experience of all of us. Still we know that some cases are curable, others amenable to treatment. The accidents Heberden speaks of are the various incidences of the arteriosclerotic, such as hemorrhage of the brain. And it is remarkable to see in such instances how a heart which but yesterday, during a paroxysm of angina, threatened to be extinguished in an instant, keeps up the current of life for days after an apoplectic attack.

The author puts the right stamp on the character of the attack when he states that angina pectoris is a spasmodic complaint. This is indeed the effect it creates, if you witness a sharp, quickly fatal attack of a sthenic nature. You see the violent spasms of the muscles of the face, the chest, the abdomen, accompanied by an overpowering expression of pain and anguish, the protruding eye, the fixed jaw, the diaphragm set to the breaking point. You hear the agonizing scream of torture and despair till the face and hands grow blue and cold, covered with clammy sweat, and the heartbeat, at first round and full and slow, becomes quick, feeble, and irregular, until the heart expends itself.

Heberden says angina is not an inflammatory complaint, although some spit up matter and blood that seem to come from the seat of the disease. Today we recognize in this symptom the failure of the left ventricle, the sudden fall of the blood-pressure, edema of the lungs.

Heberden concludes: "In opening the body of one who died suddenly, a very skillful anatomist could discover no fault in the heart, in the valves, in the arteries, or in the neighboring veins, excepting some rudiments of ossification in the aorta."

It was only a few years after the publication of Heberden's paper that the great anatomist John Hunter[2] fell a victim to this complaint. His pupil, the genial Edward Jenner diagnosed Hunter's case correctly. He had written to Heberden, stating that the cause of Hunter's attacks, as had been proven by the dissection of similar cases, was ossification of the coronary arteries of the heart; and he goes on to say: "The importance of the coro-

*Delivered before the Metropolitan Medical Society, April 27, 1915.

naries, and how much the heart must suffer from them not being able duly to perform their function . . . we cannot be surprised at the painful spasms . . . it is possible that all the symptoms may arise from this one circumstance." As Hunter turned his face toward the looking glass he looked at death itself, and when he tried to feel his pulse it was not there.

I have quoted the sources at some length and even attempted to paraphrase the essential statements of Heberden, because nothing, I venture to state, makes a subject like this more lucid than its historical aspect. The insight of the old observers often seems phenomenal—akin to divination. The subject in hand as it unravels itself in the course of the years by subsequent masters like Parry,[3] Latham,[4] Manson,[5] Walshe,[6] Huchard,[7] Nothnagel,[8] and many others, seems but an amplification of the original observations of Heberden, John Hunter, and Edward Jenner—simply an attempt to interpret the symptomatology in the light of the knowledge of each succeeding period of medical science.

To those who wish to study this subject in this comprehensive way, I would warmly recommend the "Lectures on Angina Pectoris and Allied States" by William Osler.[9] They are written in that author's most fascinating style. This little book has received a fitting appendage in his three Lumleian lectures of 1910. Neusser's[10] treatise on the subject is a classic of clinical observation. A very valuable contribution, "The Sensory and Motor Disturbances of the Heart," by Alexander Morrison of Cambridge, England, has just appeared. In the following I will attempt to sketch our modern conception of agina pectoris—the syndrome of pectoral and extrapectoral pain, as it has been gradually evolved on the basis of an extensive anatomical, experimental, and clinical experience. The latter has in no mean degree been enhanced in recent years through the actual measurement of the rise and fall of the blood-pressure during the paroxysm.

In the attempt to bring this subject to a clear understanding we encounter a number of problems, the interpretation of which is beset with serious difficulties. We must state with reluctance that, in spite of all the talent which has been brought to bear upon the elaboration of the various phases of the subject, we have not yet entered into the "essence of the matter" at hand. In trying to solve the various problems, we must be content to rest our case by bringing forward a number of theories, hypotheses, and analogies taken from the disturbances or organs like the leg or the foot—organs more patent to direct observation than those hidden away in the chest. Or we are compelled to draw upon analogies from painful disturbances of the gall-bladder, the intestine, the ureter—disturbances generally described as a state of spasm, or colic, of these organs. The principles which underlie the disfunction of these organs seem clear enough, presenting, as they do, favorable objects for comparison with apparently similar phenomena in a complicated apparatus like the heart.

Disturbance of Function.—That in one word brings us nearer than any other phrase to the general conception of angina pectoris. But disturbance of function of what organ or organs? To answer this question directly and without qualification is not possible at the present time. It would seem that Heberden stopped right here, and called the disturbance not angina cordis but angina pectoris. The changes he found in heart and vessels were insignificant. To Jenner it was reserved to find ossified coronaries, and since Jenner's time it has been generally held that angina pectoris is a disturbance of function of the coronary system of arteries, an occlusion partial or complete, gradual or sudden, of the heart's nutritional system.

The coronary theory of angina pectoris was subsequently sustained by Cohnheim[11] by means of animal experimentation. By him it was shown that the coronaries are end-arteries, so that embolism, thrombosis, or obliteration of a coronary branch generally meant heart-death, instantaneous or gradual. This theory could not be shaken by subsequent investigations, which showed that the coronaries were not end-arteries in an anatomical sense. For all practical, functional purposes, they must be considered end-arteries in the Cohnheim sense. In this way it was supposed that the painful disturbance of the heart's function was put on an organic basis. Huchard,[7] from a large personal experience and by an exhaustive study of the literature in the well-known stye of the French monograph—a work of nearly a thousand pages—sets out to prove one theme—that angina pectoris in each and every instance is caused by an affection of the coronary arteries of an organic nature.

Now if it could be proven that there are cases of angina pectoris which have been investigated by competent observers which show intact coronaries, the theory of coronary angina would not be universally applicable. That it is in fact not at all uncommon to find intact coronary arteries in angina has been known for a long time; and although coronary changes accompany other organic changes, which are to be named presently, the disorder exhibits varied anatomical substrata: organic changes of the semilunar valves, aortitis, especially in the suprasigmoid portion, the various forms of aneurysm of the aorta, to speak only of the usual well-known causes. Pathologically speaking, too, there can be no doubt of a true angina cordis. In all of these conditions, the changes in the coronaries may be insignificant.

In addition to this, it can be authoritatively stated that there are innumerable examples of subjects who harbor very material organic changes in the coronaries and who never present the symptom-complex of angina, and finally die from a variety of causes, the theory of coronary angina, though seemingly the key to the whole situation cannot be regarded as the universal or exclusive cause of angina pectoris. Or the case may be formulated thus: Coronary disease is often the *causa mortis* in persons afflicted with angina pectoris, but it is only one of various organic changes found.

After all is said, however, it would be unwise to underrate the rôle of the coronaries. In the delicate mechanism of the heart's action any disturbance of equilibrium of the coronary system, directly or by reflex, is likely to induce serious functional disturbance. Especially is this the case when the circulatory apparatus is pitched to the highest key as in the high tension of the arteriosclerotic, and additional pressure is thrown upon it through overexertion. The angina de l'effort of Potain-Huchard is the angina of high tension.

The theory of intermittent claudication, of ischemia of the heart's muscle, taken from the analogy of pain-production felt in the voluntary muscles of the lower extremities, which theory was

first presented by Charcot[12] in explanation of angina pectoris, has met with general acceptation. This theory stands and falls with the coronary theory; the limit of the one is the limit of the other. It is necessary to point out here, too, that in intermittent claudication it is also necessary to introduce an additional unknown factor to explain the pain-production, under circumstances apparently similar; presence and absence of pain under apparently identical conditions call for an additional element.

The fundamental studies in the experimental pathology of the circulation by Ludwig Traube[13] enabled this pioneer of clinical pathology to formulate a theory of angina pectoris which is representative of the views held by Parry, Stokes, and others. Traube's theory in a few words is this: Angina pectoris is the result of a violent circulatory impetus on a weakened, degenerated heart-muscle. Through the sudden influx of an increased quantity of blood into the heart, the tension of the degenerated left ventricle is worked up to a maximum; at the same time the blood flow through the sclerotic coronaries is insufficient to supply the demand of the quickened action of the ventricle. The immediate effect of the increased pressure on the heart-wall is a tearing and rending of the motor and sensitive filaments of the heart-nerves. The insufficient nutrient blood supply to the heart-muscle is the cause of the weakened heart-action. This cardiomechanic theory of angina, increased pressure on the one side, weakness of the left ventricle on the other giving rise to sensory and motor disturbances, has been adversely criticized by Fraenkel and Vierordt.[14] If weakness of the heart is the essential cause of angina, why, in a great many cases, are the objective signs of heart-weakness not apparent? A strong pulse during the attack is not unusual. The clinical paradigm of heart-weakness is not angina pectoris, but cardiac asthma. The latter not infrequently follows in the wake of an anginal attack. Functionally the two conditions are of a different portent. The painful paroxysm of angina pectoris, which, after all, is the essence of the matter, cannot be explained by the simple mechanical principles cited above. Both pain and disturbance of motility are the coordinated symptoms of an unknown noxious factor, probably of a chemical nature.

James Mackenzie's[15] theory of angina pectoris may be considered the theory of true angina cordis. The phenomenal advances of cardiac physiology and pathology, which we, in our own times, owe to the labors of James Mackenzie and many others, have among other things shown their influence in the conception of the nature of angina pectoris. By use of the sphygmographic method he proceeds to determine the functional disturbances of the various elements of the heart's musculature. As is well known, the heart's action according to Mackenzie is made up of five elements: excitability, conductivity, rhythmical stimulus, tonicity and contractility. The tracings made during an anginal attack go to show that the first three functional elements (*e, c, rs*) are intact. The loss of tonicity, too, which shows itself in a dilatation of the heart's outline, need not be present. Everything points toward a loss of contractility. This is the function which supplies the motor force of the heart, which under the circumstances, is struggling against increased resistance, and thus becomes exhausted. The sphygmographic method also shows that sometimes angina pectoris is associated with the pulsus alternaus, a sure sign of exhausted contractility. Mackenzie's theory of the rapid exhastion of contractility is in accord with the original theory of heart-fatigue of Allan Burns[16] and Lauder Brunton.[17] The origin of pain is to be sought in the disturbance of the Gaskellian function (Osler). Mackenzie himself puts it in this way: Physiologically speaking, the heart produces pain on the principle of the summation of stimuli; that is, when its contractility is forced to pass the limit of stimulation.

Ever since Heberden characterized angina pectoris as a spasmodic complaint, it has been assumed in a general way that the heart itself, during an attack, is in a state of spasm, cardiospasm, Herzkrampf. In my introductory remarks, I have tried to depict this form of angina from actual observation. These attacks look for all the world like a biliary or renal colic, like the pressing expulsive labor pains of the third stage. Now we do know that in the analogous conditions just named we are dealing with intensive contractions of the smooth muscle fibers of the gall-bladder, ureter, and uterus. Should the analogy hold good—pain production in the heart, through excessive contraction of that hollow organ—it becomes necessary, first of all, to demonstrate a system of musculature like that of the gall-bladder, etc., designed to contract violently in an effort to exert expulsive force of the kind in question. Has this been demonstrated? However that may be, cramp of the heart, whatever its nature, cannot be viewed as a tetanoid or tetanic contraction of the heart-muscle, analogous to the cramp of a voluntary muscle, induced by the electric current, for instance, as that would entail complete cessation of the heart's action. The outline of the heart by percussion and the orthodiagram, point rather to a distention than a contraction. Fraentzel's[18] acute dilatation of the heart due to overexertion is regularly accompanied by symptoms of angina. This question of heart cramp or heart colic is important, because a clear understanding of this point might go a great way in solving the whole question of pectoral pain. But unfortunately, the large subject of visceral pain and colic is still, in all its bearings, a matter of contention among physiologists and clinicians. Summing up the various hypotheses which have been put forward in the effort to explain heart-pain, we have mentioned cardio-spasm, distention, intermittent claudication and ischemia, disturbance of the Gaskellian function, summation of the stimuli or heart-fatigue. It is evident from this enumeration of essentially different, even diametrically opposed, states of the heart-muscle that the rôle the heart plays in pain-production is so far undetermined. We are plainly moving in a circle of pure conjecture.

Our knowledge of the theory of angina pectoris has been materially advanced by the study of the vasomotor phenomena. We owe this in the first instance to the genius of Nothnagel,[19] who from a number of clinical observations was led to infer that under certain circumstances anginal attacks in neurotic individuals may be induced by vasomotor disturbances of the peripheral vessels. Nothnagel looked upon these cases as neuroses of the cardiovascular system. Since then this theory has been universally applied by students of the subject as the integral factor in the production of the attack in the true as well as the false anginas.

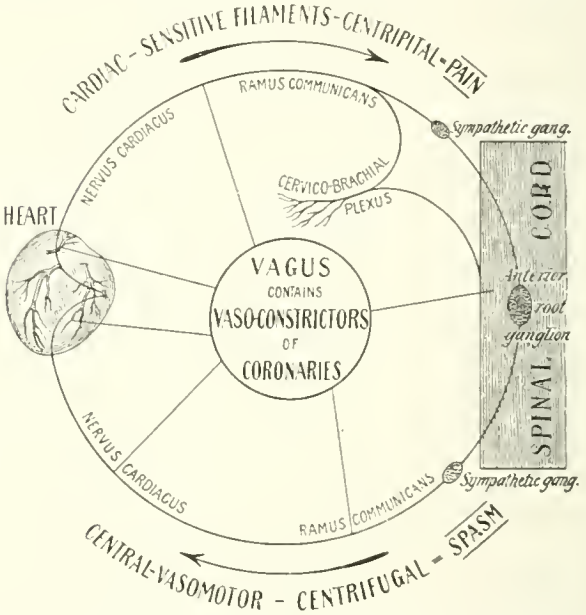
Above we touched upon the debt we owe to Traube for his studies in the pathology of the circulation. He laid down the basic principle of the rise of the blood-pressure in angina pectoris. This subject was then laid open to direct and accurate clinical observation by von Basch[20] of Vienna by means of the construction of the first clinical blood-pressure apparatus. Von Basch's work is of great value, because he controlled his clinical observations by animal experiments. That part of the work of Traube and von Basch which deals with the disturbances of the circulation is fundamental to the subject under discussion. It may be briefly stated in two words: The rise and the fall of the blood-pressure in angina; its control by the nervous system. Osler truly says: "If we understood the secrets of the rise and fall of the blood-pressure, angina pectoris would be an open book to us." Professor Pal of Vienna[21] has taken up the work of von Basch. On the basis of systematic clinical blood-pressure determinations, he has established a theory of functional disturbances of universal importance called by Collier and Pal the vascular crises. "In the course of certain diseases—nephritis, nephro-cholelithiasis, eclampsia, in the various types of arteriosclerosis, the cerebral, pectoral, abdominal, also in the arteriosclerosis of the extremities—there arise paroxysmal phenomena of the blood-vessels, spasms, and relaxations of these organs which may be termed vascular crises. They represent not a disease, but a symptom-complex on an anatomical basis; they are intercurrent phases of organic diseases." According to Pal, angina pectoris is a cardiac or a vascular crisis.

It is my opinion that the comprehensive theory of Pal in the explanation of functional disturbances is a very fruitful one in the clinic. The critical rise and fall of the blood-pressure in the anginas is one of the cardinal symptoms of these conditions, worthy of careful study, and of great practical value in therapy. Still there are cases of angina pectoris without any rise of the blood-pressure and a number of cases in which blood-pressure fluctuations are a minor feature. In my opinion the vascular crisis is a coordinated symptom of a disturbance in the nervous centers.

A complete acceptation of the arterial or cardio-vascular and *angioneurotic* theories is the work of William Osler.[9] Osler defines angina pectoris as "a disease characterized by paroxysmal attacks of pain, pectoral or extrapectoral, associated with changes in the arterial walls, organic or functional. Between heart and arteries there is no essential difference—the arteries are a long-drawn-out heart; the heart, a bulbous expansion of the arteries. They represent a physical unit controlled by an elaborate system of nerves. Any operation of the arterial system may present the phenomenon of involuntary muscle-pain," and herein, Osler thinks, lies the key to the explanation of the anginal attack. Osler also considers some forms of pain in the chest-wall, in arms, and legs as a muscle-cramp due to vasomotor spasm.

In the treatise of Neusser[10] mentioned above, which, by the way, is a mine of subtle clinical observation, that author has elaborated the paths of transmission of pectoral pain from the heart to the nervous centers and back again. This scheme is a sketch or outline of a neurogenic theory of angina pectoris. I think that I am justified in trying to establish this scheme by a name. I will call it *Neusser's anginal ring:*

"Take your starting point from the cardiac plexus of the heart, with the vasodilators and vasoconstrictors of the coronary arteries, which merge into the ganglia of the sympathetic nerve, and stand in connection with the spinal cord by means of the rami communicantes of the sympathetic. In the gray substance of the cord are found centers or paths of pain perception which in their turn communicate with the rami communicantes of the sympathetic. In this way a complete ring is formed through the connection of the cord with the sympathetic nerve in the paths of the rami communicantes. As the vagus is also included in this system, and as the vagus contains vasoconstrictor filaments of the coronary plexus, and as, furthermore, rami communicantes stand in connection with the sympathetic on the one side and the cervico-brachial plexus on the other, any irritation in this system may give rise to a typical angina pectoris, or may be produced by reflex from any part of the nervous system which stands in connection with the above. The irritation of the sensitive end-apparatus of the coronary and aortic plexus will be answered in the central organs by pain. The irri-



tation of the centrifugal vasomotor paths will give rise to ischemia of the myocardium. The anguish is produced in the centrifugal paths, including the vagus and the irritation of the medulla. Every kind of irritation in this closed ring will produce alarm in the heart and thus spinal lesions, injury to the dorsal, communicant, and cardiac nerves, neuritic affections of the aortic and the coronary plexuses, aneurysm, embolism, and thrombosis of the coronaries may produce the same symptom-complex. To this can be added the various reflexes transmitted in the paths of the vagus nerves. The result is always the same: In the center pain and fear, in the periphery vasomotor cramp and ischemia of the heart-muscle."

The difficulty of arriving at a satisfactory conclusion as to the nature of angina pectoris arises, among others, from the following considerations:

1. Angina pectoris, a clinical complex, resolves itself into a more or less definite type of functional disturbance, based upon pathological substrata of diverse kinds and various values.

2. Because heart-physiology, being a very intricate subject, is dominated from time to time by

various theories. The part played by the nervous system in the origin and control of the functions of the cardiovascular system is a matter of controversy. Yesterday we were swayed by the neurogenic theory; today by the myogenic theory.

3. Because the subject under discussion can only to a small degree be subjected to experiment.

4. Because our conception of pain, its physiological interpretation, its causal relationship as to its origin in the various tissues, its transmission from the periphery to the centers, the reflex actions produced by its emanation in the various organs, etc., are hardly understood. All this is especially the case with visceral pain. The work of Head, Ross, Mackenzie, and others has led our conception of visceral pain into new channels. The nature of visceral pain, as it is projected on the integument has been explained by Head as follows: The sensory and localizing power of the surface of the body is enormously in excess of the viscera, and thus, by what might be called a psychical error of judgment the diffusion-area is accepted by consciousness and the pain is referred to the surface of the body instead of the organs actually affected.

5. Because we possess only a superficial knowledge of the various irritations which come into play. Little is known of the rôle played by the internal secretions and their chemical modifications. An attempt has been made to explain angina pectoris on this basis. The heart and aorta, may, under certain circumstances, secrete a specific hormone which belongs to the group of sympathicotrope substances. This is supposed to exert a spastic influence on the coronaries.

6. Because what is generally called arteriosclerosis is the result of manifold biological influences and changes; it carries in its train many functional disturbances which are only being studied at the present moment.

Lastly because angina pectoris is a clinical concept. This is as it should be. It contributes to our clinical understanding to widen its scope. But at the same time it must not be forgotten that it is nothing but a symptom caused by a variety of etiological and pathological factors.

From all that has been stated above, it becomes apparent that we will never be able to understand this intricate subject unless we attempt to apply a wide clinical experience, based on searching pathological study, upon the explanation of functional disturbances in the nervous and the cardiovascular system. If we do so, we at once recognize that pectoral angina loses some of its perplexity, as it is not, as may appear on superficial observation, an affection *sui generis*, but only one of a group of similar ailments and functional import. Its workings are reducible to the same principles as the cerebral, the abdominal, the pelvic anginas. In all of these forms of anginas there must be primarily irritations of the nervous system which bring forth subjective and objective disturbances in the sensory, motor, and vasomotor centers of the cardiovascular system. The best proof of this is: Given a healthy central nervous-system and an intact cardiovascular system, anginas may be induced either directly through psychic shock or by means of certain poisons, extraneous or indigenous. Thus lead will produce abdominal and pectoral angina. Tobacco, more often than any other toxic agent, causes pectoral angina. The climacteric angina is caused by toxic substances of the internal secretions of the genital organs in the female. The result of these irritations is shown in what Solis Cohen has described as vasomotor instability or vasomotor ataxia. If the action of these poisons is eliminated perfect restitution may supervene, although it is the common experience that systemic organic changes in the cardiovascular system develop under the chronic influence of the above-named poisons. Of great interest in this connection are certain forms of anginas, pectoral and abdominal, which are of central origin, emanating from systemic disease of the cord in the tabic. They are accompanied by irritations of the anterior nerve ganglion and nerve roots. I find that they have a certain rhythmic character. The angina of the tabic may accompany, or take the place of tabic crises, and present striking vasomotor phenomena.

Summing up, I have mentioned the psychic, the toxic, the tabic, the climacteric anginas, as a proof of the primary neurogenic forms of angina. These forms are sometimes called pseudo-anginas, a name which is indispensable in practice. But that does not change the principle of their constituting forms of angina of a primary neurogenic origin.

Notes on the Pathological Aspect.—Angina pectoris is mainly associated with changes in the right side of the heart and the aorta. The work of Heller and Doehle on specific disease of the aorta has lately received well-merited attention. Specific aortitis is a frequent source of breast-pang. Specific neuritis of the plexus and nerves of this portion of the aorta occurs relatively early in luetic disease. Rheumatic infection on this site, though denied by some, frequently leads to anginoid attacks. Allbutt[22] has gone so far as to point to root affections of the aorta as the universal cause of angina pectoris. Two observations have been repeatedly noted: in aortic insufficiency the anginoid pains tend to subside when compensation has set in. In aneurysm the sharp pain diminishes when the specific process in the intima has passed the acute stage. I always look for anginoid pains in acute pericarditis. These pains are more often localized in the shoulder. This is important, because in stout individuals the diagnosis of a pericarditic exudate may be difficult, and shoulder pain may give the first clue to the condition.

The Importance of the Infectious Element as the Immediate Cause of the Attack.—In my personal observations, I have been struck by the frequency of the infectious or post-infectious element in producing the attack of angina. You will find only scant reference to this subject in the literature. In many instances anginoid symptoms are the introductory signs of an acute infection. Pneumonia, typhoid fever, enteritis, but above all influenza or pseudo-influenza, gave the impetus in my cases in predisposed individuals. The statement that angina pectoris is a non-inflammatory complaint must be modified in the sense I have just mentioned. Careful measurements will elicit temperature fluctuations of one, two, and three degrees, preliminary to and during the course of the attack. The so-called status anginosus—the recurrent phase of angina—is accompanied by a low temperature movement, indicating an inflammatory process in the cardiovascular system and elsewhere. Leichtenstern,[23] Sansom,[24] and others mention the frequency of angina during the great epidemic of influenza. Sansom has post-mortem findings of recent aortitis. I would accord to the infectious element the most important intercurrent rôle in bringing on the attack of angina.

Therapeutically, I consider morphine a specific. The nitrites are indicated in the spastic forms which are associated with high pressure. Repeated doses of the nitrites should be carefully controlled by the blood-pressure apparatus. When heart-failure threatens all the heart-stimulants are indicated. Traube thought that digitalis may cause angina pectoris. I have seen at least one fatal case after long-continued use of digitalis in a predisposed individual. Neusser administers it in cases with low pressure. I have used it again and again with good result. The blood-pressure apparatus should be used constantly as a gauge of the pressure fluctuations, as a guide to prognosis and therapy. I have also used Nauheim and Pyrogen baths with excellent results

In conclusion I give a brief statement of my conception of angina pectoris:

Angina pectoris is a syndrome or clinical complex, made up of pectoral and extrapectoral symptoms, subjective and objective. These symptoms are the expression of disturbances in the nervous system. They are called forth by irritations of various kinds, which act directly or by reflex upon the nerve complexes—peripheral, regionary, and central—of the sensory, motor, and vasomotor apparatus of the cardiovascular system.

Angina pectoris is a symptom of great dignity clinically, on account of its effect upon the heart. The heart is directly or indirectly implicated, and will, in the last instance, determine the outcome. A degenerated heart, a heart with degenerated coronaries, will react, in proportion to the amount of reserve force it is able to exert. If the reserve force is small, death follows from heart insufficiency either directly by syncope or more gradually by heart decompensation, cardiac asthma, hypostasis, pulmonary edema. On the other hand, angina pectoris may originate in, be transmitted to, disfunctionate, play itself out in the nervous system, and kill by vagus inhibition, or paralysis of the nerve-centers.

I am not able to follow Osler[9] when he says angina is a disease with a definite morbid anatomy. To my mind angina is a clinical complex with the characteristics discussed above, which is superimposed upon divergent structural changes in various tissues of the pectoral viscera, the most common of which is arteriosclerosis of the coronary and the aortic system. Neusser[10] has taken great pains to bring forward remarkable cases of angina pectoris, the lesions of which were exclusively in the pectoral system of nerves.

There is no reason in my opinion why we should not consider angina pectoris, first and last, as a disturbance of neural values. There is no organ more rich in nerve fibers than the heart. The heart contains sensory nerve filaments. A cardiac angina in the true sense is therefore not only possible but probable. The cardiovascular system is under direct control—from within and from without—of the vasomotor system, regionary and central. The vasomotor system reacts directly upon the sympathetic, as well as by reflex, and vice versa. Abdominal, cerebral anginas originate in the same way. The heart itself, though it is the most important link in the chain of the mechanism of angina pectoris is primarily not essential in the causation of the attack.

Osler bases the angioneurotic theory, in part, on the analogy with Raynaud's disease, and Buerger's[25] work on vascular disease. Raynaud's disease, according to Osler, affords the best illustration of disturbance of sensation as a direct result of angiospasm. The paroxysmal character of the attacks, the intensity of the pain, the direct association with angiospasm, suggest its vascular origin. Most investigators are agreed that the vascular changes in Raynaud's disease are intercurrent and primarily have no bearings on the etiology of the disease itself. According to Cassirer and Buerger, Raynaud's disease is an affection, the lesion of which resides somewhere in the central nervous system. The pathological process in Raynaud's disease, according to Buerger, is to be sought in the vegetative system, the vasomotor apparatus. The vasomotor and trophic disturbances are the outcome of irritative and exhaustive processes of the sympathetic system.

Mackenzie[26] brings an interesting example of a case due to excitability of the vasoconstrictor mechanism in insufficiency of the aorta, due to an irritable focus of the central nervous system at the origin of the nerves whose peripheral ends are hyperalgesic. Verdon [27] looks upon angina pectoris as a tetany of the gastroesophageal sheet of muscles, a habit-neurosis due to the presence of foci of irritation at the segmentary centers of the cord. Schmoll's[28] observations led him to the same conclusions. Gibson[29] cites cases of trophic disturbances in angina pectoris in the muscles of the arm and forearm as well as dilatation of the pupil and prominence of the eyeball, all symptoms pointing to sympathetic involvement.

And now I come back to my introductory remarks. Heberden first recognized a distinct functional disturbance of the chest and looked into the cardiovascular system for an explanation of this strange spasmodic complaint. Edward Jenner, with the eye of the genius, at once accounted for it by the organic change in the coronaries. Both conceptions, spasm, and sclerosis have been deepened and widened by the research and experience of a century and a half.

No doubt we have learned a great deal. But let us be fair and confess, are we any nearer to the essence of the matter? When Jenner says how the heart must suffer, and when we try to express the same thought by the terms, cardiospasm, angiospasm, vascular pain—are we any nearer to a real understanding of the subject? I am inclined to reply in the negative. I would say, spasm of the heart—if that was in Heberden's and Jenner's mind—still awaits positive proof. It is my opinion that the visible spasmodic symptoms of the sthenic form of angina pectoris are probably nothing more than an Abwehrbewegung—a defensive movement called forth by pain, so vividly presented by Crile[29] in his latest work on the emotions. And as to spasm of the vessels—angiospasm—let us grant that with a mental reservation. We are dominated to-day by the myogenic theory: we ascribe functional disturbances in the cardiovascular system mainly and primarily to the irritation of the muscle-fiber. This is, I think, a one-sided view. In speaking of the heart-nerves Mackenzie says there is a great deal of evidence which is entirely lost to the physiologist, but which is open to the clinician. The changes that result from the stimulation of the cardiac nerves cannot be ascertained by experiments on animals, he says, nor as far as I myself know by the histologist.

To my mind, the essential element in angina pec-

toris, as well as in all anginas, lies in the irritation of the nervous system. What we generally understand when we speak of angina pectoris probably belongs to the group of diseases which go under the heading of exhaustive diseases of the nervous system.

A STUDY IN THE INTERNAL THERAPEUTICS OF RADIUM.

By SAMUEL DELANO, M.D.,

BOSTON, MASS.

In connection with this summary of the first Boston application of radium emanation therapeutics, it ought to be borne in mind that nothing has been used alongside that could in anyway influence results; neither drugs, nor in general any of those physical adjuncts such as change of air, of scene, of regimen, or of habits, that are so often pointed to as the real efficient agents in treatment at spas.

One important particular distinguishes this series from previous ones, viz., the mode of exhibiting the radium (*sc.* radium emanation). Radium emanation may be introduced in several ways, viz., by injection, by inhalation, by bath, and in solution by drinking. But rarely, however, has it been given conjointly with its source, radium, because this yoking up has not until now been generally available.

Loewenthal in his "Grundriss" endorses this, however, as the most desirable method of exhibiting emanation, viz., a radium salt in solution, which, after sealing, has produced the emanation within its own precincts.

In such a case there is present, after a month, that amount of emanation which is in equilibrium with the radium salt (what may be called the maximum-equilibrium-constant) and there is also the radium salt as well. This last has an infinite capacity in emanation and must give off a further amount in its passage through the body.

One microgram of radium referred to (abbreviated 1 mcgm. = 1/1000 of a milligram) means a solution of enough of a radium salt to yield that equivalent of radium element. The amount of emanation in equilibrium with this one microgram of element is a microcurie, the measurement of which is 2,700 Mache units.

The cases are not in any sense selected. On the contrary, it seemed worth while to take them as they fell—failures, successes, slight or complete. This, because of the novelty of the subject and the meager use as yet made of radium emanation in this country.

Moreover, even if some of the cases are very thin in clinical results, they at least show that radium can be taken without untoward effects. In this connection, too, it may be said that the earliest cases have been observed for a period of eighteen months.

Rheumatism and Gout.

Case I.—*General Debility with Gouty Tendency.*—F., æt. 54. Pain in back of head—great toe reddened and sensitive—some eczema about foot, of long duration. Took 2 mcgm. radium daily and 3 radium baths a week. After about a month much improvement with disappearance of local signs in foot. Radium markedly diuretic and laxative. After four months, repeated for tonic action only. Then again in eight months with a swollen finger joint. On the third treatment writes, "There is no doubt that for me radium is a good tonic."

Case II.—F., æt. 46. Pain in back of neck with creaky vertebræ and knees. Had persisted good while—other treatment ineffective. Two micrograms of radium, sometimes three daily—60 altogether. No creaking in knees—very much improved—markedly laxative effect. Three months later remains in unusually good health without symptoms.

Case III.—*Gout.*—M., æt. 46. Previous history of three attacks of gravel with two small stones—large patches of eczema—pruritus ani for a year. Intestinal putrefaction with very loose discharges—foul breath and tongue—neuritis in shoulder for a year. Radium at three different times—(60 micrograms over space of six weeks) in course of year—completely freed from pruritus and eczema; marked tonic action; better condition of bowels and sweet breath. Had radium by cataphoresis for shoulder; neuritis has disappeared.

Case IV.—*Chronic Rheumatism Four Years.*—M., æt. 24. Motorman; pain in back, toes and wrists; interfered with work; much treatment including Mt. Clemens; 36 micrograms radium and one dozen radium baths in three weeks' time. At expiration of this time showed much improvement; gain in weight; amelioration of dyspepsia. Six months later continued well.

Case V.—*Rheumatoid Arthritis.*—M., æt. 72. All joints especially hands and knees; distortion and increase in size; unable to sit down in a chair, dress himself, or go downstairs. First week sharp reaction; seventh day, "first good day"; in three weeks, after 36 micrograms radium and 12 radium baths, dressing himself every morning, coming downstairs alone, getting down in chair and up, and going out. Marked diuretic effect, interfering with sleep; also excitant. Lost sight of.

Case VI.—F., æt. 50.—*Recovering from acute rheumatism.* Patient in bed but with normal temperature; radium produced reaction with temperature 100°. Patient soon up, which the physician attributes to radium.

Case VII.—F., æt. 82.—*Sciatico.* Headache, depression of spirits; under radium (two micrograms increased to six) in all 384 micrograms over period of ten weeks. Nurse reports enthusiastically; absence of pain and headache; much better look; more energy and able to do more. The physician reports that patient "bothers" him much less.

Case VIII.—Physician, æt. 50. *Rheumatism in hip;*

painful and an inconvenience. Orthopedist, after exhaustive examination, called it rheumatism. After month, patient reports many good days; says radium certainly stirs him up; produces reactionary pains in other joints; distinctly diuretic; is now taking larger doses. Second report: after taking 288 micrograms over eleven weeks; thinks it has done him good because less acute pain.

Case IX.—F., æt. 55. *Chronic progressive rheumatism;* swelling of wrist; example of postponed action. After 36 micrograms radium over a period of three weeks, physician thought there was not much result, though swelling of wrist was less in a few days. Four months later reported very enthusiastic over radium; "had cured her rheumatism" and sent word to Case VIII to persist.

Case X.—F., æt. 50. Wife of physician; mild *arthritis deformans* (chronic progressive) of fingers; took 24 micrograms radium without admitting benefit.

Case XI.—F., æt. 55. School teacher; over weight; pain and lameness in hip, making it difficult to get about; some months duration; took 36 micrograms radium and one dozen radium baths; three months later writes as if benefited.

Case XII.—A peculiar affection of hips characterized by adduction of the thighs. Took 24 micrograms radium and 2 radium baths. Physician reported after several months that treatment had apparently produced an improvement.

Case XIII.—F., æt. 65. *Chronic progressive rheumatoid arthritis.* All joints affected; enlarged even to twice normal; one and a half years duration; has been lifted out of bed in morning and placed in chair where she sat until put back at night; fed for six months. Complete atrophy of muscles; contraction of ham strings; parchment condition of skin; pronounced an "impossible case" by an experienced clinician. Radium by intravenous injection; four of 50 micrograms over a period of four months. Immediate improvement showed itself; able to feed herself using both hands on tenth day. Improvement continued fairly steadily with some interruption; in three months got out of bed alone; seven months from date of first injection—having had no radium for three months, the hands and feet are free, with much more movement in shoulder and knees. There is an absence of pain in joints, but patient is troubled by a stitch-like pain in back, which interferes with her rising or sitting up as much as would be otherwise possible. Remarkable improvement has occurred in general condition; color; nutrition of skin and hair; appearance again of perspiration in feet; gain in weight with a stimulated appetite from the outset. She is able to use a needle; the very latest developments have been (8 months after the first radium) appearance of perspiration of feet and cracking of shoulder joints. Much freeer mobility of knees without resistance of hamstring; absence of pain complete; feet natural; as far as joints are concerned, could walk, but very little muscle development yet; greater degree in arms. This a hospital case, observed by five physicians.

Case XIV.—F., æt. 60. *Chronic rheumatism* with much pain; took 24 micrograms radium distributed over three weeks; well-marked improvement and relief of pain. One month later her physician reports her as marveling "that so much benefit could have followed use of what seemed merely water"; diuresis in this case.

Case XV.—F., æt. 54. *Rheumatoid arthritis.* Took 72 micrograms radium distributed over three weeks; patient had no faith and was reluctant to take. Was not observed very much but the physician said that two months later he could not get patient to admit more than an early and passing improvement. Four months after radium treatment patient had uterine hemorrhage; polyp was removed; on further hemorrhage, scrapings were reported on adversely, and to give benefit of doubt, an hysterectomy was done and a virgin uterus removed.

Case XVI.—M., physician. æt. 57. Weight 225; inherits rheumatism; his own form is of chronic progressive type; shoulder and hips. Took 48 micrograms radium by mouth over space of six weeks. Felt that it stirred him up; was markedly diuretic; had many ups and downs as to pain. At end of four weeks better than for long time; where he could not get leg across to put on slipper can now almost shoulder the limb; marked improvement in digestion in respect to flatulency which had been very marked and annoying—an enormous appetite which he has to restrain. Verdict six weeks after, was that he was better than he had averaged and that radium had done him good. [Note:—The amount of radium seemed by no means proportioned to the case or the man; it may have been just enough to keep condition stirred up well without proportionate curative effects.]

Case XVII.—F., æt. 48. Heavy person; *sciatica* and pain in hip; under care of osteopath. Took 24 micrograms radium and one dozen radium baths over space of about two months with intermission. The physician's conclusions were that the treatment had a favorable effect. The stimulant action was noticeable and care had to be taken as to overmuch excitation.

Case XVIII.—The patient middle-aged club man; accustomed to liquor; full of fugitive pains; was well relieved by radium (36 micrograms in three weeks), which in a way took the place of liquor; six months later he wanted the physician to order radium for his wife.

Case XIX.—Physician's wife, æt. 40. Painful knee; not incapacitated; was decidedly relieved by 24 micrograms over three weeks; well marked laxative action, missed by patient after leaving off.

Case XX.—F., æt. 70. Took 48 micrograms radium over six weeks; nurse reported very enthusiastically over results. The patient reported she had no "catarrh" while taking (previously constantly complained of); influenced by results in this case, another person in the house resorted to radium.

Case XXI.—F., æt. 40. Pains in fingers; took 60 micrograms radium over space of three weeks; reported much relief, though physician remarked that he did not think much was the matter.

Case XXII.—M., æt. 28. *Chronic progressive rheumatism.* Fingers and ankles swollen; had had vaccine; when seen, dilated heart, excited action; souffle; well-marked cyanosis of nails and prolabia. Took 36 micrograms radium over space of four weeks; in ten days marked improvement. Heart down to normal dimensions, steady at 70; very much improved color. On a slight relapse became discouraged and his physician had him go to a hospital and have tonsils removed as the primary source. But, two months after leaving hospital, he again wanted radium for its tonic effect and took some. After four months is about free and in improved condition but says he will have radium intravenously in case of recurrence. In this case it is certainly open to doubt whether the cure may not be placed to radium.

Case XXIII.—M., æt. 32. An acute exacerbation of *gonnorheal rheumatism* affecting especially wrists; 36 micrograms radium irregularly over four weeks. A very undependable patient, but the verdict of his physician was that it had been of benefit.

Case XXIV.—M., æt. 30. Ball-player; arm crippled with pain; took 12 micrograms radium; was immediately better and both his physician and himself ascribed the cure to radium.

Case XXV.—M., æt. 25. *Gonorrheal rheumatism* of three or four years' duration, with remissions. This attack of six months' duration; quite crippled, swollen tarsus and toes and tendo Achillis; painful hips and shoulders; marked anemia and loss of weight; not worked for four months; vaccines and other treatment. Fifty micrograms intravenously; after reaction, first improvement in a week; in two weeks so much benefit that patient "crazy for another." Another 50 micrograms given at twenty days' interval from first; quite pronounced reaction again but in six weeks very great improvement with no swelling of foot and almost no lameness, but swelling and tenderness of clavicular joints. At this time a rheumatic iritis developed; was given 15 micrograms radium and at date of writing has been at eye hospital; improvement in joints continues; on leaving hospital reported improvement.

Case XXVI.—M., æt. 25. Very severe *gonorrheal rheumatism* of six months' duration; not worked for four months; thickening of one knee; swelling of tendo Achillis and of tarsus, pain in insteap making it impossible to stand; treatment by specialist including much vaccine. Fifty micrograms intravenously; thought a little improved and wanted another. Fifty micrograms given at three weeks' interval. At six weeks the physician and himself found difficulty in seeing improvement; no change in weight but laces his shoe tighter and knee, perhaps, a little less swollen but cannot stand; therefore cannot resume work.

Case XXVII.—Elderly woman with *rheumatic arthritis,* especially affecting neck which was painful and offered difficulty in moving. Twenty-four micrograms radium over three weeks and radioactive earth ef-

fected much improvement according to both patient and doctor.

CASE XXVIII.—F., æt. 35. *Infectious rheumatism* after birth of child; seven years duration. Chronic progress leading to ankyloses; knees bent to almost right angle (these have been operated on at Johns Hopkins Hospital). Right arm has very little motion (from shoulder) so that she can just get it to mouth; with left, this is impossible. Fingers distorted; some flexed, some extended. One hundred and fifty micrograms radium; three injections over space of three months. Improved after first with mitigation of pain and better nights; wanted another. Three months after beginning of treatment there is a little improvement. Is having 10 micrograms injected about left elbow. One cannot speak of much result in this case after a longer observation.

CASE XXIX.—F., æt. 40. Wife of physician; had been much troubled with pain in joints; no other (objective) symptoms. The physician had tried many things but said she had improved much under radium; 36 micrograms over four weeks; it was markedly diuretic.

CASE XXX.—Patient an old lady with *rheumatic arthritis* and double senile cataract. The case may be related in the doctor's own words. Five weeks from inception he writes: "There was in this case a marked reaction in the joints and muscles lasting four or five days, severe enough to keep her awake nights, attended with a slight fever and marked anorexia. This reaction was followed by a rapid and very decided improvement in all the joints so that she was soon walking about and down to the dining room (by elevator). However, coincidently with the arthritic improvement she developed a state of most intense nervousness and irritability which was most trying. From being most considerate, sweet, and patient she became utterly unreasonable, wakeful, extremely nervous, and 'touchy.' This change of disposition was quite persistent so that I finally omitted the radium after having reduced it to 2 micrograms a day. The nervous excitation gradually subsided, so that lately she has been in that resnect about as usual. After leaving off the radium, however, her joint symptoms became worse again and after a few days I resumed its use, giving 2 micrograms a day. About a week ago we were out of the radium for two days. To make up for that I gave her 4 micrograms a day for two days when starting it again. That has been followed by a moderate joint reaction. but without so far any reaction on the part of the nervous system and I have reduced the dose again to 2 micrograms daily." One week later the doctor writes: "My patient continues to gain now without further reaction, slowly to be sure but gratifyingly." Two months later: "She has improved immensely; from being practically helpless, goes out for short walks every few days, dresses herself all but her hair and except for more or less aches at night, feels fine."

CASE XXXI.—F., æt. 70. Physician's mother; general arthritic pains; no objective signs; chronic; accustomed to daily dose of deodorized tincture of opium, as high as 90 minims. Ten micrograms radium given twice subcutaneously at weekly intervals. Six weeks after the doctor reports the patient had experienced relief.

CASE XXXII.—M., æt. 50. Gout; right great toe swollen and tender; leg swollen; confined to bed; two previous attacks; one lasting six weeks. There is already some improvement under other treatment. Intravenously 25 micrograms radium; 12 micrograms by mouth; in four days resumed work and improvement was continuous and lasting. Twenty-five micrograms intravenously repeated in ten days; reported well on sixth week. Complaint of palpitation at night.

Neuritis and Neuralgia.

CASE XXXIII.—M.; *Neuritis* of arm; of some duration and some time under treatment. Took 12 micrograms radium; 1 microgram daily; physician said patient reported entirely cured.

CASE XXXIV.—F.; *Neuritis* of arm; three weeks duration with pain, tenderness, and paresthesia; 24 micrograms internally; also locally three different injections of 10 micrograms each; at expiration of ten days patient so much better she did not want the third injection. A month after, no recurrence and the doctor prescribes radium for another patient.

CASE XXXV.—M., æt. 35. *Neuritis;* previous attack of neuritis eight years ago, when in bed four months; present attack seven months' duration. Severe pain in left arm requiring anodyne and making nights sleepless; arm markedly swollen; hanging at side; entirely immobile at shoulder; (has been advised by surgeon to have operation on bursa and joint); fingers glazed and tense; jaundice six weeks ago; sugar reaction in urine (also for four years). Two micrograms radium daily with radium compress; after four days swelling decidedly reduced; fingers wrinkled; bones of elbow showing; arm can be moved from side sufficiently to cleanse axilla (before impossible). After this, continued use of radium internally, of compress, and in addition three different injections about shoulder of ten micrograms of radium each. Steady improvement with rapid subsidence of pain; out in eight days; back to business in twelve days (away from business six weeks); in a month rarely pain; arm now discloses atrophy of muscle from disuse; can now button shirt and tie scarf; marked improvement in sleep, looks, digestion, tongue, and breath (odor). In six weeks joint quite movable. Has taken 144 micrograms radium with 30 injected. In two months continued increased motion; pain absent. Six months later the patient has remained well. The arm has free though not perfect motion at the shoulder.

CASE XXXVI.—Neuralgia; with postoperative conditions after excision of glands. Patient had local process in cheek; ulcerated plaques cauterized several times. Finally submaxillary gland removed by incision; histological report malignant. Injection of alcohol for facial neuralgia produced paralysis of fifth nerve. This patient had fresh scar of recent operation (two lymphatics), facial paralysis, and neuralgia. Had radium pad of 50 micrograms; scar retracted and organized unusually promptly; developed another enlarged gland; had improvement in neuralgia for three weeks with some relapse in fourth; recovered use of facial muscles; three weeks later recurrence of pain; ten weeks after commencement of treatment had taken 240 micrograms radium. In fourth month the case looks like recurrent malignant disease of jaw.

CASE XXXVII.—M., æt. 55. *Epigastralgia* and chronic neuralgia radiating to arm; angina; brother of physician; number of years duration; last six weeks very severe in morning; interferes with exertion; has to stop; much belching of gas which relieves pain. Diagnosis, calcification of coronaries and angina (with bad prognosis, by prominent consultant. Heart is small, at apex second sound accented; no impulse felt by hand; nothing about aorta; no general atheroma; blood pressure 120; chronic scaling eczema of face. After four weeks (96 micrograms radium) apparent improvement; has days of entire freedom; eczema much less evident. Heart has enlarged, there is some impulse and first sound has some booming character and carries the accent. Pressure increased as high as 220; artery much fuller to touch. Pain recurring, patient left off radium. After six weeks of increased suffering, sudden death supervened.

CASE XXXVIII.—F., æt. 35. *Neuritis*, arm; has had several attacks and they last several weeks. This attack quite similar to the others and for a few days used other remedies. Then radium was substituted. Took 24 micrograms radium and used radioactive earth locally. Both doctor and patient were of the opinion that the case was controlled by radium; both because of relief and short duration.

CASE XXXIX.—F. *Facial neuralgia.* Took 24 micrograms radium and used radium compress without relief. *X*-ray showed unerupted wisdom tooth which seemed an efficient cause for the neuralgia.

Nephritis and Metabolism Cases.

CASE XL.—*Interstitial nephritis marked arteriosclerosis.* F., æt. 70. Chronic invalid for some years; confined to room; increasing edema of ankles; decreased amount of urine; very marked anemia. Under radium continuously for three months, about 190 micrograms being taken. There was the most remarkable improvement; edema disappeared; urine increased from 15 to 45 ounces and maintained itself; great improvement in appetite, color, and spirits. Urea also was measured and showed increase. The patient got enough better to go out riding. The radium was omitted for a couple of months. Patient had suddenly uremic convulsions with pulse of 150 of great irregularity, and complete suppression: she seemed about to die. Radium was resumed cautiously and her condition rapidly improved. The doctor and the family paid the greatest tribute to the treatment.

CASE XLI.—M., æt. 68. *Catheter-life case.* A year previously the question of prostatectomy had been

raised but decided negatively on the ground of poor work by kidneys. There was an analysis made immediately previously to taking radium. Two micrograms daily was given for a week; at the end of that time the urea and uric acid showed an increase of 50 per cent. For some reason the radium was omitted but the physician inquired some time later if the radium was cumulative inasmuch as the urea and uric acid and amount had continued to increase and the showing became quite satisfactory. The patient, however, was seized by an obstinate singultus to which he later succumbed.

Case XLII.—M., æt. 12. *Essential diabetes* with accompanying parenchymatous inflammation of the kidneys. The patient was lethargic, moped, and it was for this that the radium was prescribed in the hope of getting a stimulant effect; it was an unqualified success so that it was kept up for a couple of months. The effect on the sugar excretion was also appreciable; a quantitative analysis was not made, but the somewhat increased amount of urine was reduced to normal and the qualitative test was less marked. The patient was lost sight of.

The story of these cases recounts not much more than the simple, familiar, clinical facts of everyday practise. To some, the glamour of laboratory tests being wanting, they may appear not complete—perhaps not scientifically precise. But there is still a large place for empiricism in medicine.

Radium can reduce blood pressure, but there was no opportunity for such specific applications of it. So likewise radium has marked effects on the blood picture, but no cases of pernicious anemia or leucemia offered themselves. For the cases in general, then, observations along these lines would not be likely to add much of value. So our cases are clinical pure and simple. No doubt many will scent a strong "psychical" odor in them. In quite a proportion of the cases, however, there were decided features of an objective character, whose disappearance concided with the general relief.

In our quest for greater socalled scientific precision in the shape of objective laboratory findings we are in danger of making "subjective" tantamount to "psychical." No doubt it is much to be desired that the highly complex phenomena of radium's action be coordinated. But this consummation, though devoutly to be wished, appears to be a long way off. But many disturbances of the economy of sufficient proportions to constitute a morbid state and to make a patient of a person, are purely subjective, *i.e.* divorced from objective phenomena. The disappearance of these states is no less an ostensible cure, without quibbling as to its demonstration, or classifying it as psychical.

And yet it may be that in the case of radium emanation we are face to face with a greater consonance of behavior, outside and inside the body, than in all drug therapeutics put together. For radium is unique in being a force and in expressing itself by liberating energy, which in turn is capable of measurement. This idea of introducing a force into the body and more particularly in the form of a solution, is more or less puzzling because unfamiliar; but the "idée mère" of radium internally is to make the blood radioactive through the presence of radium emanation—a radioelement characterized, as all radioelements are, by its instability and its certainty of passing over, according to its own law, into the next radioelements in the scale—this transmutation, decay, or resolution, to be attended by the liberation of rays and energy.

This idea of a force, once seized upon, not only makes the effects of radium seem consistent, but it puts radium therapeutics into the category of natural and physical means, as contradistinguished from drugs—nay more, it even links up the use of emanation internally with the use of radium for irradiation, since they both have the common purpose to produce a biological recoil on the part of the tissues.

Radium emanation we ought to challenge with three distinct interpellations: in its use, there are three distinct propositions involved, viz., Does it do anything, what can it do: and can it do harm?

Those who have assumed to think of radium-emanation-therapeutics as a myth, a mere piece of emptiness, are entitled to another guess. Radium internally is a real remedy? It is not inert! It has potentialities that make it both useful and beneficent, though its action may at times be mystifying, indeed, a bit uncanny.

It is to be emphasized, however, that we have in mind a solution of a radium salt, which alone gives an assurance of permanence and dependability. Much of the disappointment and contradiction of the past hinges on the unreliability of emanation as divorced from its parent and source, viz., radium.

What can radium emanation do as revealed in this series?

1. *It is diuretic.* This is, perhaps, the most consistent single effect of radium. The ratio is, perhaps, in seven out of ten cases. This feature may be rather rapidly produced or show in any pronounced way only after three or four weeks. It would not seem to be ascribable to direct action on the kidney because radium is not excreted to any extent by the kidney. Some investigators have altogether denied the possibility of radioactivity in the urine. A recent very reliable estimation gives (after intravenous injection of a soluble salt) a recovery of 1.88 per cent. only, after three days: most of which is on the first day. If diuresis is not to be ascribed to local action, it can be referable only to general influences, such as systemic effects or changes in the constitution of the urine.

2. *It is laxative*—not so often as it is diuretic, but in a good percentage of cases. This does not mean that it procures loose motions but only what seems ascribable to quickened peristalsis. A recent investigation of great accuracy shows that after intravenous injection of a soluble salt there was recoverable in the feces on the first day 17.9 per cent. and in four days 43 per cent. This item of excretion by the intestine has a somewhat important bearing because of the possibility of irritation. The same holds true of thorium X (the radioelement of the thorium series, which is used internally). This has been accused of doing much damage by producing congestion, hemorrhage, and gangrene with, it is alleged, resulting death in some cases.

Nothing of the sort has been observed by us. One case, however, pointed in this direction:

Case XLIII.—F., æt. 70. In the last years much pain of a rheumatic nature; enormous varicosity of abdominal veins; in last two months two outbreaks of purpura, legs and abdomen, spots size of silver dollar, now fading; took only 18 micrograms radium over space of two weeks, when an ounce of bright blood escaped spontaneously from rectum; never had had any hemorrhago. [Of course there is the possibility of connecting this with the purpura, which however, was not active.]

Cases XIII and XXVIII, in which the largest amounts of radium were used, and that intravenously, both had, about six to eight weeks after the first injection, almost a week of colicky diarrhea; they were both in bed at the time. This phenomenon was very suggestive of the elimination of radium.

3. *It is tonic and stimulant.* Remarkable is it

with what consistency one may predict that radium will make a patient look and act better. As a direct hematinic it is indisputable that radium will stimulate a pronounced increase of red cells and hemoglobin, so that cases of pernicious anemia rapidly lose their perniciousness (if we may not speak of cure). This direct effect on the blood would not, however, seem to be the whole story, inasmuch as there appears to be an independent stimulant action. Some patients have spoken of a heating influence, and in Case XLVIII, even after a long period of use, the dose had to be reduced on that account.

Case XLIV.—M., æt. 60. Physician; very nervous; had some pains and got an idea of trying radium; took 36 micrograms radium in a month's time; it was during extremely hot weather which was particularly trying to him; the verdict was that the immediate effect of the radium was to increase nervousness.

See also Case XXX for a remarkable observation along the lines of ultrastimulant effect. Even more striking is the following:

Case XLV.—M., æt. 85. Senile with marked atheroma; the senility was of the harmless variety and the patient went about the house and to meals. Radium was ordered and four micrograms given in two days; the patient became violently excited, singing and shouting; a nurse had to be retained and the patient restrained. There had never been any manifestation of this sort before and the condition passed promptly on suspending the radium.

This tonic and stimulant effect, while not to be regarded as reflecting the most essential physiological activity of radium, is, nevertheless, a very important and satisfying exhibition. It seems to distinguish radium from drugs, where the by-play is, to speak broadly, depressant and harmful. Thus, to take that chief of alterants potassium iodide (this being in a measure analogous to radium) in securing our effects from the iodine we have to submit with patience to the deleterious influence of the potassium.

The effect of radium in the matter of increasing sexual vigor (a part of its reputation that is historical and on which von Noorden lays stress) has not been observed, though not specifically inquired into. One case was treated with this attainment in view:

Case XLVI.—M., æt. 40. Complete sexual incapacity for a matter of fifteen years, during which he had been under observation by a specialist; from 48 micrograms of radium over a month's period he had no change to report.

4. *Metabolism and nutrition.* Here we are approaching the copestone of the arch of radium's psysiological action. While it is true that the physiological action of radium may not have been so thoroughly studied as perhaps it some time will be, there is not much dispute as to its increasing the nitrogenous metabolism. Outside of the body it is marvelous in catalysis and autolysis and in the intensifying of fermentative and digestive processes. What it does on the laboratory table it would seem likely to repeat inside the body (which so often is not the case), because it is present in the system in the same unchanged form.

Radium from this standpoint may be looked upon as stimulating to the innumerable ferments of the body: as supplying a goad, so to speak, to the vital processes. A corollary to this would be that it ought to be an equalizer, tending to restore the balance of forces. Very interesting in this connection are the observations on the heart in Cases XXII and XXXVII. If these observations are correct (the reporter is responsible for them) then, while taking radium, one heart very obviously increased its dimensions while the other decreased—with a correspondence of collateral signs that was strongly corroborative. Granting that the fundamental effects of emanation are on metabolism, this would give it a very wide range of applicability with which it seems proper to credit it; especially, it may be repeated, as it does not have the disturbing by-play of drugs.

Its action on rheumatism and neuritis is probably through its attacking the inflammatory conditions and promoting absorption and excretion. Bactericidal action within the body, though demonstrable to a good degree outside, is probably not to be reckoned with. It would not be surprising if in the future some relationship of radium to the ductless glands were to be made out, as for example, to the adrenals.

The effects of radium on nutrition of the skin seem to me very happy. Old skin brightens up and looks younger. In Case XIII (under observation ten months) this feature was very pronounced. At the outset, the patient could have been pronounced a mummy; the skin was atrophic and parchment-like; it is now soft like a child's. The nails commenced to grow and require attention and the feet to perspire. One observer using radium for rheumatism found an acne rosacea improve; and in an old lady (where the tonic effects were pronounced) brown spots on the face cleared up.

Case XLVII.—M., æt. 55. Apothecary; *General eczema* (called psoriasis because so scaly); two months previous treatment with arsenic; on 36 micrograms radium cleared up absolutely in three weeks.

See Case III for eczema and pruritus. A case of psoriasis of 17 years' standing, now being observed by a specialist and under treatment by intravenous injection (95 micrograms radium thus far) has shown a remarkable and immediate improvement.

In our series of neuritis and rheumatism cases the results have been such as to point to a considerable degree of control by radium over the conditions. As in so much of the task offered to radium (and this is even more true of the radiation of neoplasms) nothing is bequeathed to radium until it is wellnigh hopeless. Many of the cases have been rheumatoid with much change in the anatomy. Perhaps the time will come when radium will be offered something easier. Falta uses emanation in acute rheumatism and prefers it to the salicylates.

In general it may be said that the nearer the joint is to a "juicy" stage—periarticular or intraarticular edema or effusion, the more pleasing the prospect.

The neuritis cases have all done well. Case XXXV was really brilliant. The more of an inflammatory element the better.

As a pain killer radium has great power, but in the case of nuerotic neuralgia in highly nervous individuals the outlook is not so good.

Case XLVIII.—Fractured hip in an old withered limb; patient up and about in spite of it, but suffered much pain at night; was much relieved by radium and took it for six weeks or more; it was quite excitant.

5. External and topical. Even a weak solution (2 micrograms to 2 ounces) is anodyne. We can testify from personal experience to its instant relief of toothache; this a dentist has confirmed in

several instances. Held in the mouth for a few minutes a small quantity of the same solution will produce, not immediately, but after some hours, stiffening of the mucous membrane, swelling and blanching of the lip, viscidity of the pharyngeal mucus, and it almost seemed, a little clumsiness in speech.

Saliva diluted with water will be very foul in forty-eight hours; diluted with radium solution (amount of radium 1 15,000 mgm.) it will remain unchanged a week.

Case XLIX.—F., æt. 10. After incising a fat boil on the lip (size of the tip of the little finger) I applied solution of radium (2 micrograms to 2 ounces) as a moist dressing. The boil was entirely dry, scabbed, and insensitive in eighteen hours. The patient later volunteered the information that "the scab was white."

Case L.—Ivy poisoning; the rash failed to mature and the itching was much relieved; in this case also; there was a dry white skin at the point of greatest intensity.

Case LI.—Pyorrhea alveolaris; a tooth inflamed to extreme tenderness, very loose with gum beefy and with an alveolar abscess, which two dentists said would be lost, is now relatively firm and entirely serviceable. In this case a solution of radium (25 micrograms to 2 c.c.) was packed beneath the gums and this same solution was used in the nerve cavity after excavating. Solution of radium (2 micrograms to 2 ounces) was used to rinse the mouth.

In a metropolitan surgical clinic all pus cases have been trated with solution of radium (2 micrograms to 2 ounces) and the control of radium over the process has been surprising.

Chronic empyema of the accessory sinuses (cures of which by radium internally have been reported) have been treated in two instances.

Case LII.—*Purulent catarrh of the antrum and ethmoid;* a year's duration; operation advised by several observers, but refused; treated for a number of months by injection without improvement; put on radium solution internally with injection of the same (2 micrograms to 2 ounces); after four weeks the doctor reported the amount of pus in the wash water as reduced one half with the advent of what was apparently cholesterin; the patient said she felt better. For some reason in spite of this improvement (which was confirmed by nurse assistant) treatment was not persisted in.

Case LII.—M., æt. 45. *Empyema of antrum causing vertigo.* The patient, a physician, was obliged to relinquish work; abscess drained and washed out with solution of radium (2 micrograms to 2 ounces). The attendant says the case did extremely well. The vertigo promptly disappeared and the patient has no symptoms. After two months there is a very slight discharge in the washings.

Dosage.—In making a radium salt form the basis of dosage, it must be borne in mind that the amount of emanation present is subject to a definite law—it cannot be more than the equilibrium quantity, which is a fixed constant. Quite otherwise is it with emanation *per se*—the amount of which present can be increased ad infinitum. The basis of comparison between a solution of a radium salt and a merely radioactive water (emanation) is quite unequal. For, the moment the emanation of the raidum salt solution is separated or transmuted—more will be furnished to take its place. Thus a solution of a radium salt has potentially a reserve supply of emanation which for the time being yields no units of electrical measurement.

In the preparations used in this series the maximum of emanation had already collected and thus in association with 1 microgram of radium we have one microcurie of emanation or 2,700 Mache units by measurement.

Some of the radioactive springs of Europe have an almost ridiculously small emanation strength (a few Mache units to the liter). Results have been claimed from them nevertheless. When now we turn to such doses as 1,000,000 to 1,500,000 Mache units of the London Radium Institute, no wonder that the older observers are inclined to apply the term "psychical" to their early results.

From this wide range of extremes it might seem as though there was nothing fixed about the dosage of radium. No doubt the dose is more or less flexible. The very high doses came about through the influence of thorium X, the cheapness of which gave the desired opportunity for forcing the pace. But the experience was a thorny one. Injury and death were confessed to and warned against by the very users. Since then the tendency has been towards lower dosage just as in the use of radium salts for irradiation. Moreover, the men of longest and largest experience are saying that they obtained equally good results with the small as with the larger quantities.

Our own experience in the above cases has shown that the adjustment of quantity to the case is a matter of nicety and calls for judgment.

Of the very large doses it may be said that, if radium is selective, a really superfluous and unutilizable quantity may have been introduced with the bare result of a mere waste of ammunition. One has to be on the look-out, no doubt, for something corresponding to the action of radium in irradiation, viz., in one case stimulation, or absorption, and disappearance of morbid processes in another.

One puzzling part of the application of dosage is the production of reaction either to an undesirable degree or prolonged. It then becomes a nice question whether to leave off or to increase the dose.

The cases related had many of them this essential drawback, that the treatment could not be prolonged or the dosage pushed at will on account of the expense. So that in of many of them, we may say there was no proper try-out and that results are merely fragmentary. The duration of a radium cure, if for well-established and intrenched conditions, ought to be from two to three months. Moreover, the maximum effect does not always coincide with treatment and there may be even a delayed improvement setting in only after cessation.

Without any question we have seen some such exhibitions. This is, perhaps, more likely to occur where a radium salt is taken, because of the greater possibility of accumulation. None can be predicted as possible with emanation simply, but only the retention of some of the later radioelements in the scale.

Proescher and Viol have shown that, following injection of a radium salt, radioactivity may be demonstrated in the organism after at least three months, and that by far the largest amount of radium may be recovered from the bone and bone-marrow, where it has been deposited in the form of an insoluble salt.

The average dose with which we have tried to work has been about 4 microcuries daily, viz., about 11,000 mache units. (In Kreuznach, where radium treatment has been most systematic, the daily dose is from 5,000 to 15,000). A smaller dose and for a shorter period has seemed to render service in some mild conditions. It is quite clear that the attempt to crowd the dose, in a certain proportion of cases at least, may throw the patient into a decidedly upset state. There may be lassitude and a decided lack of energy or a mere state of ner-

vousness. The experience with these cases has seemed to teach the lesson of approaching the maximum dose very gradually.

But nothing is to be expected from a low dose and short period of administering in serious chronic conditions. Thus there had been four cases of paralysis agitans which it did not seem worth while to include because there was no really serious or consistent employment of the treatment. It is to be said, however, that in two of them a stimulant action could be noted and a rally from the extreme depression. I have seen one case under much longer radium treatment in which the patient so far improved as to be able to feed himself and to go about, neither of which things was possible at the commencement.

The object being to introduce the emanation into the blood, lodging it there by the immediate route of the vein is, of course, the method par excellence; hypodermic or deep injections would come next and giving by the mouth last. Here, owing to the extreme diffusibility of the emanation, there is a considerable portion of it lost without passing into the systemic capillaries. Subcutaneous or deep injection gives some share to local action, although it has been shown that a soluble salt does not linger long.

Can radium internally do any harm? We have not been able to detect any traces of damage. Under the skin and intravenously there is nothing in the way of local reaction and it is certain that we can introduce into the blood good large quantities without particular reaction. Pains may be touched up, but of constitutional disturbances there is no evidence. Cameron and Proescher have given 1,800 injections of radium salts over a space of two years and in quantities up to a milligram without observing the slightest injurious effects.

Administering *per os* has perhaps one advantage, viz., its local action on stomach and digestive tract. The influence here is undoubtedly considerable and favorable.

In conclusion it may be said that this experience has served to teach that radium emanation (and the same thing is true of irradiation) calls for one requisite that makes it in a way ill-adapted to the American temperament, viz., patience. That one should attempt to disturb a profound, well-intrenched chronic state, with a week's use of radium is as puerile as to set off firecrackers and assume to call it an assault on the citadel.

The impression which it is desirable to make, whether we are using radium externally or internally, is essentially biological, *i.e.* morbidity is to be made to reform itself by a process originating in its own bailiwick. Here the initial performance would undoubtedly be to set in motion just those processes that could acquire momentum and propagate themselves, viz., a cellular recoil. In either case, within or without, radium is to be looked at as just the goad or stimulus to the self-regenerating apparatus.

At all events, the radium question is here and it will be settled and settled right. That will take time and a heap of patience. To this end open mindness is a great desideratum. Above all, systematic use of it after every fashion on an ample scale is to be hoped for. To be this, in respect to emanation, the above series could, of course, scarcely make claim, but as an initial try out it may prove of interest and we hope a little importance.

39 Newbury Street.

OPERATIVE ORTHOPEDICS AS ILLUSTRATED BY A HOSPITAL SERVICE.*

By ROYAL WHITMAN, M.D.,

NEW YORK.

Modern orthopedic surgery begins, it seems to me, with the plaster jacket and the traction hip-brace, since these were the means of demonstrating in a popular sense that the only remedy for deformity was the effective treatment of the deforming diseases. In the development of this larger field of activity so many unsuspected or neglected causes of disability have been identified that tuberculous disease has become, numerically at least, of minor importance in orthopedic practice.

As a necessity of comprehensive treatment, operative methods have been utilized and devised to supplement or supplant mechanical correction and support, and as a consequence, braces of the complicated and cumbersome type once associated with the purely mechanical treatment of deformity are no longer in common use.

At the present time it is, I think, generally recognized that orthopedics is the mechanical specialty not because it is restricted to mechanical methods in treatment, nor because its field is limited to actual deformity, but because it is concerned with the mechanics of the body, and particularly with the diseases of the locomotive apparatus.

Many of these affections appear in early life and are of a chronic character, consequently their remote effects upon the disabled part and upon the development of the body must be considered in selecting the immediate treatment. Thus one who practises orthopedics should be familiar with the mechanism of the body and with the natural history of the diseases that disable it.

Such knowledge can be acquired only by actual experience and long continued observation, and this is perhaps the most reasonable explanation of the growth of a specialty which has no definite boundary from medicine or surgery.

The earlier orthopedists, as a class, were content to demonstrate the merits of "mechanico-therapeutics," and some of their successors continue the same practice, supplemented, it may be, by subcutaneous operations, or by so-called bloodless surgery. On the other hand, operative treatment is often undertaken by those who are unfamiliar with the characteristics of the deforming diseases, and untrained in natural mechanics. Under such conditions the immediate effect of an ill-advised operation may be mistaken for a lasting one, or if of proper design it may fail for want of subsequent care and protection. Thus because of lack of training or inclination, lack of experience, and above all, lack of opportunity for comparative tests, this branch of orthopedics is still in the tentative stage.

It has been suggested that an analysis of the operative routine at representative hospitals would present the subject in a manner favorable for discussion from the comparative standpoint, and that this might be a step toward the more general acceptance of certain basic principles in treatment. As a contribution to this end a report of a recent service at the Hospital for the Ruptured and Crippled is presented.

*Read before the New York Academy of Medicine, March 18, 1915.

The founder of this hospital, both by inclination and conviction, represented what is called conservatism, and for many years it had no provision for operative work. At the present time neither adult males nor children under four years of age are admitted to the wards, a restriction that limits traumatic cases and congenital deformities in early life, notably club foot and dislocation of the hip. Otherwise every facility for immediate treatment and subsequent supervision is assured.

The service to be reported (June to November, 1914), including the vacation season, when the wards are usually free from contagious diseases, is a very active one, and while a review of the entire year would be more representative of the hospital, it would lack the personal element so essential in the discussion of the comparative merits of one or another operative procedure.

In this period of four months the entire number of operations was 609. Of these 198 were in the hernia service, and 16 were on the nose and throat, leaving 399 classified as orthopedic. One hundred and forty-three of these were open operations. In 136 the cutting operation was of a minor character, including osteotomies, tenotomies, and the like, and in 120 the deformity was corrected by the so-called bloodless methods.

Many of the operations are sufficiently standardized as to require no special comment. For example, 45 patients were operated on for rachitic deformities of the extremities by osteotomy, and 12 by osteoclasis. Osteotomy is preferred for the correction of the resistant and localized distortions, and osteoclasis for those of the more yielding type.

There were comparatively few important operations for tuberculous disease, since a large proportion of such patients were in the country. Two of these were resections of the knee in adults, and one a resection at the hip in a child, incidental to securing proper drainage.

There were four Albee transplantation operations for Pott's disease. All of these were for well-marked and progressive deformity in the dorsal region, requiring the removal of curved sections of bone from the tibia, for which, in my opinion, the electric saw is almost a necessity. Three of the patients were adults who had never been treated, one of whom was paraplegic. I prefer this operation to that of Hibbs in cases of this type, because of its more positive assurance of immediate and permanent support. It is especially indicated for disease of the dorsal region in patients of advanced development. I do not think the operation will ever supplant mechanical treatment, or that the results of an ankylosing operation can equal the natural cure in cases of the favorable class, in which almost perfect motion is sometimes retained. The routine treatment of Pott's disease in early life should be rest on the convex stretcher frame during the active stage of the process, supplemented by efficient support when ambulation is resumed. If the plaster jacket is to be used the Calot modification is to be preferred.

There were twenty-one operations for the correction of deformity complicating tuberculous disease of the joints, including seven osteotomies of the Gant type.

The common distortion at the hip is flexion and adduction. This in uncomplicated cases—that is to say, quiescent cases free from suppuration—is immediately reduced under an anesthetic, the limb being fixed in a long plaster spica in hyperextension and about 15 degrees of abduction. As a rule, there is but little pain or other reaction after the operation. If the head of the femur is destroyed, with upward displacement of the trochanter, osteotomy is indicated, since otherwise recurrence of deformity is inevitable. Correction of deformity by the weight and pulley, although satisfactory if the distortion is due chiefly to muscular contraction, is not usually effective in securing what may be termed over-correction. In these resistant cases the traction force, if effective, must be so great that it is, in itself, an irritant, as indicated by the increased sensitiveness of the joint.

Manipulative correction has the great advantage of enabling one to fix the limb immediately in the desired attitude, whereas the traction treatment requires long confinement to the bed even for incomplete rectification.

When the limb is placed in marked abduction pressure is removed from the diseased area, and is transferred to the outer border of the neck. The importance of this attitude in relieving pain and preventing the destructive influence of pressure and friction during the progressive stages of the disease is, I am sure, not generally appreciated.

In the routine of outdoor treatment the limb is fixed in complete extension and about 15 degrees of abduction by a plaster support of the Lorenz type. Ambulation is permitted if it causes no discomfort, long spicas, rest in bed, traction, and the like, being employed at discretion during the acute phases of the disease. The principles of treatment, as regards activity, are those in force for the similar disease of the lungs. Locomotion, if properly regulated, is of great value in preserving the nutrition of the limb, which in the days of the traction hip splint was often neglected.

Flexion contraction at the knee is corrected by what I have called reverse leverage, which prevents subluxation when the limb is straightened. If the deformity is of long standing the contracted tissue should be divided as a preliminary measure.

There were twenty operations for congenital dislocation of the hip, twelve by the Lorenz method, and eight by arthrotomy. It is apparent that the congenital dislocations should be treated, and in the large proportion of the cases cured before the age of four, the majority of the cases admitted being, in this sense, of the unfavorable type. I shall consider only the open operations. In six of these the cause of failure of previous treatment apparently was anterior torsion of the femur. In all the Hoffa operation was performed, the acetabulum being made more capacious, especially at its upper margin, with the aim of assuring retention. The results in such cases are usually good, in the sense of security and comparative freedom of movement, apparently because the forward twist which prevents accurate adjustment lessens the danger of ankylosis. Osteotomy with the aim of restoring the normal relation of the neck and shaft without arthrotomy is not usually successful because the acetabulum is too shallow to contain the head. One operation on a large girl fifteen years of age was for the relief of disabling pain on use. Reposition in this case was very difficult. The last was for dislocation complicating anterior poliomyelitis. In this case the capsule was overlapped in addition to deepening the acetabulum.

There were two operations for ununited fracture of the neck of the femur in adolescents, both of

whom had received treatment in other hospitals. In one the neck had been almost completely destroyed by friction. The surfaces of the fragments were freshened and they were apposed and fixed by a spike driven through the base of the trochanter.

This is the sixth case of non-union after fracture of the neck of the femur in early life due to inefficient treatment that has come under my observation and under this head I class all methods except that by abduction. The other fracture was of the epiphyseal type, the neck, still adherent to the head, being displaced forward and upward. In this case in the absence of friction there was no bone destruction—"spontaneous absorption." The normal relation was restored by separating the fragments with a chisel and by abducting and rotating the limb inward.

The third arthrotomy was in a boy of twelve who had for several months limped and complained of pain in the limb, apparently as a result of injury. The *x*-ray picture showed what was interpreted as incomplete fracture and displacement. This on inspection proved to be an actual distortion or flattening of the head with no evidence of injury or disease—an example, apparently, of what the Germans call incongruity.

There were two operations of arthroplasty at the hip. The first was on a young woman, both of whose hips were fixed by bony anchylosis with the limbs crossed, as a result of disease in childhood. The head on one side was chiseled free from the acetabulum and a pedicled flap of fat was interposed. The adduction deformity and an accompanying equinus were corrected two weeks later. Treatment of the other hip is to be deferred until the control of the new joint is established. The second case was also one of bilateral fixation in flexion and adduction in a girl of twenty, the result of an open operation for congenital dislocation in pre-Lorenz days. One side had already been operated on by another surgeon with the insertion of pig's bladder. This one was treated by the fat flap method.

There was also an arthroplasty for bony ankylosis at the elbow in a girl of 19, following tuberculosis. In this case a free flap of fascia from the thigh was inserted. The free fascia method is to be preferred in cases of this type because the tissues about the joint are insufficient for the purpose.

There were three other arthrotomies, one for correction of deformity following fracture at the elbow and two for chronic synovitis at the knee.

There were six operations for torticollis. The contracted muscles and resistant fascia were, in all cases, divided through an oblique incision just above the clavicle. The deformity was then thoroughly over-corrected by forcible stretching and the head was fixed in the over-corrected attitude by a plaster Minerva. The support is retained for several weeks until the new attitude is thoroughly impressed upon the tissues. The after treatment consists in methodical manipulation, stretching, and exercises. No brace is required, except in the treatment of young children.

The only other operation of importance on the upper extremity was the transplantation of the trapezius for deltoid paralysis. This aids in supporting the arm and increasing the power of abduction, although it cannot replace the function of the deltoid.

A large proportion of the remaining operations were in the lower extremity. Three of these were for ununited fracture of the leg bones, two being treated by bone transplantation—the so-called inlay method. It would seem that eventually fractures will be treated by those who are qualified by technical training and knowledge of natural mechanics. Under such conditions the legitimate field for operative intervention will be much restricted and the operations will be performed under more favorable conditions than at present.

There were 63 operations of forcible correction of deformities of the foot combined in many instances with subcutaneous division of contracted parts. Of these 9 were for congenital club foot, 12 for rigid flat foot, and the remainder for paralytic distortions. In many instances the correction in this latter group was preliminary to other operations, such as tendon transplantation.

Forcible correction, or rather over-correction of club foot followed by fixation for a sufficient time to permit reconstruction of the internal structure and the restitution of normal function is most satisfactory in its results if properly performed. Operations on the bones of young children, at least, should be of a supplementary character.

There were two Phelps' operations for resistant varus, one so-called "evidement" of the interior of the resistant bones to permit collapse, and two cuneiform osteotomies.

There were a large number of tenotomies incidental to the correction of deformity. Twenty-six of these were of the tendo achillis, which is usually divided subcutaneously because of the ease of performance and slight disturbance of the tissues. The deformity having been corrected, the foot is fixed by a plaster support. Functional use is encouraged as early as possible, since weight bearing aids in adapting the foot to the new attitude and stimulates repair. Under ordinary conditions there is practically no danger of non-union or of an elongated or weakened tendon, although this must be considered in spastic cases, or if the contracted muscle is weak or paralyzed.

Most important numerically is a group of 60 operations for paralytic deformity of the foot, grouped for convenience under the author's name as the Whitman operation. Its basis is astragalectomy and backward displacement of the foot. The displacement is of vital importance since without it the removal of the astragalus would be of little value. Tendon transplantation and the like are supplementary procedures.

The first essential in the operative treatment of paralytic distortions of the foot is to assure security, since uncontrolled movement causes instability and deformity. By removing the astragalus the malleoli may be implanted on the basic structure of the foot, thus assuring lateral stability, and by displacing the foot backward the scaphoid may be brought into direct contact with the tibia. This checks dorsal flexion at a right angle and provides a resistance that restores the lifting capacity of the limb. This operation is curative in the sense that it restores stability without ankylosis, improves function, and enables the patient to discard mechanical support.

The preservation of motion, as compared with arthrodesis, which in cases of extensive paralysis is the only other method that may assure stability, is of great advantage since it enables the patient to wear a shoe adjusted to an attitude of plantar flexion that will compensate for shortening of the limb due to loss of growth. The most common criticism that I have heard is that removal of the astragalus

shortens the limb. This is only partly true, since the typical operation is on a hollow foot to which symmetry is restored. In any event the shortening is but slight and of little importance compared with the obvious advantages that could not otherwise be secured.

The operation was originally designed for deformity of the calcaneus type, but it has since been employed for every form of paralytic distortion of the foot. In fact, of the 60 operations, but 16 were for calcaneus, in which the typical transplantation of the peronei tendons into the tendo achillis was carried out.

In 28 cases the paralysis included practically all the muscles, and there was no tendon transplantation. In 8 of these the deformity was of the varus, and in 8 of the valgus type. In 16 cases the operation was combined with tendon fixation, the paralyzed peronei tendons being sewn into a groove or grooves cut in the fibula, according to the Gallie method, with the aim of checking the inclination toward varus. This, however, is of comparatively slight service because if the foot is properly displaced backward even the insertion of the brevis is but little in advance of the external maleolus while that of the longus is below it.

In certain of these cases the paralysis was practically complete of one or both limbs, the object of the operation being to restore the symmetry and stability of the foot, so that a brace might be worn with comfort.

This procedure, which was first described in 1901 (*Am. Jour. Med. Sci.* Nov., 1901), has steadily grown in favor, since it has the great advantage over all other operations for paralytic distortions of the foot that both its immediate and remote results are practically assured, even if the after treatment is neglected, and that it enables the patient to discard support even if the paralysis of the foot is practically complete. The method has been carefully described (*Annals of Surgery*, Feb., 1908; *Am. Jour. Orthopedic Surg.*, Aug., 1910; MEDICAL RECORD, Jan. 10, 1914) and these details should be followed.

The joint must be exposed by the long external incision, so that the foot may be completely dislocated inward, to prepare the new articulations, and to free the malleoli completely in order to permit backward displacement sufficient to bring the external malleolus directly over the calcaneo-cuboid articulation.

This displacement, which is the keynote of the operation, is apparently rarely carried out to the proper degree, except by those who have received direct instruction on the subject and frequent admonition.

The last group to be considered is of 42 cases of tendon and muscle transplantation. Five of these were of the biceps, three for paralysis of the quadriceps extensor, and two for spastic contraction. The insertion of the biceps is separated from the fibula, and the muscular substance dissected from the femur as high as the middle of the thigh, in order that the full length may be obtained, and that the line of pull may be as direct as possible. An incision is then made above the patella through the quadriceps tendon and the underlying capsule, without disturbing the synovial sac. A second lateral opening is made in the capsule through which the tendinous insertion of the biceps is passed, and is then drawn out between the divided quadriceps tendon, to which, and to the periosteum of the patella, it is firmly sewn with silk. No silk prolongation of the muscle is required, as the tension is not greater than is desirable, nor can there be danger of detachment or stretching. This operation is of great value in increasing the stability and resistance of the limb when it is extended in standing and walking, and it usually enables the patient to dispense with support.

In spastic cases the chief cause of deformity is removed, and the balance of power is in some degree restored. The two operations for this ability were on one individual, and were combined with other transplantations of the muscles of the feet. In one case of extreme spastic constriction excision of the knee and astragalectomy were combined in order to make the limb useful as a support.

There were 20 operations for varus deformity, in 4 of which it was a remote result of the operation just described for calcaneus, the direct cause being the transplantation of the peronei into the tendo achillis. The power in these cases was rebalanced by transplanting the tibialis posticus into the tendo achillis, and the tibialis anticus to the outer border of the dorsum of the foot. There were several operations in which both the tibialis anticus and posticus were transplanted to the outer border of the foot for the relief of spastic varus, and others in which the tibialis posticus was displaced forward of the tibia to serve as a dorsal flexor and adductor in cases of valgus. The peroneus brevis also in connection with the tibialis posticus may be displaced forward of the malleolus as an aid to dorsiflexion. In several cases the longus hallucis was transplanted to take the place of a paralyzed tibialis anticus, which was either shortened, or fixed to the tibia. In operations of this class the astragalo-scaphoid joint is opened, and the ligament overlapped, or if the bones are sufficiently developed an arthrodesis is performed at this joint, as an additional safeguard against valgus.

There were also three independent tendon fixations for paralytic varus. This operation, recently advocated by Gallie, consists in implanting the peronei tendons into a groove or grooves cut in the fibula, and there sutured into place under sufficient tension to hold the foot in the desired position. Thus a useless tendon is transformed into a useful ligament. This operation is somewhat on the line of the silk ligament, but in my opinion greatly to be preferred. Assuming that a silk cord attached to an active muscle may be transformed eventually to fibrous tissue, it by no means follows that one joining bone with bone as a passive support will undergo such transformation. On the contrary the change to be anticipated in buried silk is disintegration, as has often been demonstrated by later examination. Silk ligaments may be serviceable as temporary supports in connection with braces, but it seems unlikely that they will be sufficient independently and permanently to resist the tendency to deformity.

This completes the list of operations that it has seemed desirable to analyze in a paper of this length. They are of course so recent that they can only serve as a text for suggestions and conclusions based on previous experience. It is obvious also that a report of a single hospital service cannot adequately represent the field of operative orthopedics, although it may seem to illustrate in a general way its scope and character.

283 LEXINGTON AVENUE.

PUBLIC HEALTH OF OTHER AGES.

By HOWARD D. KING, M.D.,

NEW ORLEANS, LA.

THE common law of health, the Christian law, "Thou shalt love thy neighbor as thyself," is coeval with man and society. In fact, the problems of public health were as well known to the Ancients as to the present day observers. It is a well accepted axiom that no epidemic can gain headway with clean houses, clean air, and clean water. Sickness and death, like the evil demons of old, shun cleanly places. In olden times, as among the Jews, evil spirits dwelt in filthy places, especially loving tombs and ordure. Every latrine contained a special demon of its own, and does to the present day in a different sense. It is quite evident that the chamber of Sara, the daughter of Raguel, as described in the book of Tobit, overlooked a dunghill, otherwise she would not have been so grievously afflicted by Asmodeus, who, out of love for her, strangled her seven husbands. But Tobias, her eighth husband, for whom her father-in-law considerately dug a grave as soon as the marriage was performed, obviously knew that there might be smells even too bad for a demon, for, on the bridal night, he threw the putrid heart and liver of a fish on some burning embers in her chamber, and, as the narrative tells us, "the which smell, when the evil spirit had smelled, he fled into the uttermost parts of Egypt." Without question, the book of Tobit is a distinct hygienic allegory. The good Tobit had a craze for burying dead bodies, and had all his troubles in consequence of his hygienic propensities. Sleeping in a foul place, the sparrows muted warm dung into his eyes, and rendered him blind. But Raphael, whose name, by interpretation, means "the medicine of God," comes as an angelic guide to his son Tobias, and puts all things right by his hygienic knowledge—conquering even the foul demon Asmodeus and curing Tobit of his ophthalmia.

The ancients combated evil odors more vigorously than the moderns. Sometimes, indeed, they simply tried to mask them with perfumes. Thus, when we hear that ancient Capua had whole streets filled with perfumer's shops, we are certain that it must have been a foul smelling and ill-governed city. If you were to ask a present-day sanitarian the best means of deodorization he could not give simpler or better ones than those of Ulysses, as described in Homer. After slaughtering Penelope's suitors, and scattering their blood and brains over her spacious halls, he first makes a thorough cleaning:

"With sponges they rub the tables o'er
(The swains unite their toils); the walls, the floor,
Washed with the effusive wave, are purged of gore."

And it is only after thus thoroughly removing every origin of bad smells that he uses a disinfectant to destroy any foul gases which might still lurk in the room:

"Bring sulphur straight, and fire, the monarch cries:
She hears, and at his word obedient flies,
With fire and sulphur, cure of noxious fumes,
He purged the walls and blood polluted rooms."

Contrast the proceedings of the wise Ulysses with those of Eidothea, the daughter of the old sea-god. She fell in love with Menelaus, who, with his two companions, was cast upon the island of her father. To conceal them from the old sea-god, she wrapped them in the skins of fresh flayed seals, and made them lie among the flock. Menelaus groaned under the horrid smell of his disguise, till the divine lady brought a powerful scent to mask the putrid odor:

"Dire was the ambush, and the scent severe,
Who could a rank sea-beast at such close quarters bear?
But she, delivering us, a great help planned,
And placed ambrosia near the lips of each,
Which in our nostrils breathed an odor bland,
And the sea monster's stench did overreach."

Ulysses was an excellent hygienist, but Eidothea was not. The first went to the root of the matter and removed all sources of impurity; the latter merely concealed a stench by perfume. Hercules, too, was one of the oldest and most thorough of the ancient sanitarians. He saved the Eleans from pestilence by draining their marshes, and executed a thorough sanitary operation when he cleansed out the Augean stables by turning into them the waters of the Alphaeus. But of all sanitary reformers, Moses was among the most practical. He was learned in the wisdom of the Egyptians, and they, as we know, were hygienists. One of their commandments, though it does not remain among the ten which Moses brought down from the Mount for our guidance, was, "Thou shalt not pollute rivers." The hygienic laws of Moses, supplementary to his ten moral commandments, are full of wisdom. The purifications required by religious observances were in the main hygienic precautions. The ceremonial part still remains in the East as a survival of a purpose which is now forgotten. Moses gave to us the principle of the modern earth closet, and excellent rules for isolating and disinfecting diseased patients and their excreta. He established health-officers, or, rather, gave to the high priest the function of an officer of health. Today we have been obliged to enact, or, strictly speaking, reenact the ancient laws of Moses relating to the isolation of infectious diseases.

During the best times of Greece and Rome, public health was much studied. The anatomical and pathological examination of the intestines of sacrifices was a hygienic precaution to ascertain whether the locality upon which a city was to be founded or a camp pitched was in healthy condition. The supervision of hygienic arrangements was an office of dignity among the Greeks and the Romans. Epaminondas, one of the greatest military geniuses that Greece produced, did not refuse the office of "telearch" at Thebes, though its chief duty was to supervise the cleansing of the streets. For this Plutarch justly commends him. In like manner, at Rome, the cleansing and disinfection of streets and sewers were placed under a high officer of state, because as Justinian tells us, "uncleansed and unrepaired sewers threaten a pestilential atmosphere, and are dangerous." Of the surviving works by which the greatness of Rome is still evidenced, perhaps, the first is the civil law, but second stands its sanitary works, as manifested in the great aqueducts, the cloaca maxima, and other hygienic appliances. It is, then, clear that the ancients knew as well as the moderns the main conditions of public health; viz., that dirt is the source of disease, and that cleanliness is its preventive. And so the sum and substance of all our sanitary science accumulated by ages may be summed up in the pregnant advice of the prophet—*Wash and be clean.*

A few illustrations of the consequences attending

the neglect of the hygienic maxim—*wash and be clean*—are, at this juncture, timely and interesting. When the civilization of the Egyptians, the Jews, the Greeks, and the Romans faded, the world passed through dark ages of mental and physical barbarism. For over a thousand years there was scarcely a man or a woman in Europe that ever took a bath. How diñerent that time was from the times which preceded it—when daily baths were common among the poor—one may gather from the praises of personal ablution which abound in ancient authors. Take, for instance, Martial's address to his friend Oppian, on the limpid and unpolluted water in the Virgo and Marcian wave, in which it was rapture to bathe:

"Water so bright, and clear, and fair,
You think no liquid can be there;
You're not attending, Oppian,
You'll die without once having washed, poor man!"

But only think what must have been the state of Europe when thirty-three generations were like Oppian, and never once washed, if their historian Michelet is to be believed. Small wonder then that there came the ravaging epidemics of the middle ages, which cut off one-fourth of the population of Europe. But even when the middle ages had passed away, and the sun of civilization was again rising over the gloomy darkness of these centuries, what a heritage of filth-produced disease still remained. Ponder over Defoe's or Montaigne's description of the plagues of their day. It is not a pleasing task to dwell on the filthy habits as practised in those dark days. Go back only to the time previous to the Reformation, and one can have no difficulty in understanding why luxury and squalor produced the plagues of the times of the Tudors and the Stuarts. Filth, instead of being abhorred, was almost sanctified. The monks imitated the filthy habits of early Christian times, for the early fathers commended them. Even St. Jerome used to praise the filthy habits of hermits. He especially commends an Egyptian hermit who combed his hair only on Easter Sunday, and never washed his clothes at all, but let them fall to pieces by rottenness. St. Antony never washed his feet. St. Thomas à Beckett, when martyred, had undergarments in a state which makes one shudder in the remembrance. And so the monks up to the time of the Reformation thought, or professed to think, that by antithesis, pollution of the body indicated cleanliness of the soul. Practically, indeed, it helped to it; because the odor of sanctity, which infested these old monks and hermits, served to keep them apart from worldly temptations; for the world cared not to come into too close contact with them.

Hippocrates, who was the first hygienist that wrote a book on public health, took as his text pure air, pure water, and a pure soil, and to-day we have arrived at nearly the same view of the essential conditions of health. Later, much later, Coleridge, who evidently had some ideas of his own anent stream pollution, commented in this strain on the foul smells of the city of Cologne:

"But tell me, Nymphs! what power divine
Shall henceforth wash the river Rhine?"

Congress must enact for this country the ancient commandment of the Egyptians, and say to all municipalities and manufacturers, "Thou shalt not pollute rivers." If Congress achieves the purification of our rivers, the Government can be assured an amount of applause, which can best be expressed in the words, if not in the meaning, of Macbeth, when he says:

"Come, sir, despatch; if thou couldst, doctor, cast
The water of our land; find its disease,
And purge it to a sound and pristine health,
I would applaud thee to the very echo
That should applaud again."

In ancient as well as modern hygiene the importance of an adequate ventilation of streets and houses was well known. It was also a matter of recognized experience that even efficient ventilation of these would be of little use unless the ground on which they were built was also ventilated—that is, drained of underlying water. Zeno ordered that houses in Constantinople should be twelve feet apart, and not more than nine stories high. Augustus limited their height to seventy feet, and Trajan to sixty feet. High-handed Queen Elizabeth was so horrified with the growth of her capital, London, although it then contained only 160,000 people, that she forbade the erection of any more buildings within three miles of London and Westminster, and she prohibited the division of a house into tenements for various families, "because great multitudes of poor people inhabiting small rooms, and those very poor, and such as must live by begging or worse means, being therein heaped together and in a sort smothered, with many families of children and servants in one house or small tenements, it must needs follow that if plague or sickness came amongst them, it presently spread through the whole city and confines."

A DIAGNOSTIC SIGN IN INFLAMMATORY CONDITIONS AND TRAUMATISMS IN AND ABOUT THE LIVER.

By MILTON R. BOOKMAN, M.D., F.A.C.S.,
NEW YORK,
ADJUNCT ATTENDING SURGEON, LEBANON HOSPITAL.

THE liver, situated as it is beneath the dome of the diaphragm, does not lend itself readily to the touch of the palpating fingers except at its free border and when the organ is enlarged, but with the method herein described some of the inflammatory and traumatic conditions in and about the organ may be rendered more easy of recognition at the bedside.

The falciform ligament (broad or suspensory ligament) is a broad and thin anteroposterior peritoneal fold, falciform in shape, its base being directed downward and backward, its apex upward and backward. It is attached by one margin to the under surface of the diaphragm, and the posterior sheath of the right rectus muscle as low down as the umbilicus; by its hepatic margin it extends from the notch on the anterior margin of the liver as far back as its posterior surface. It consists of two layers of peritoneum closely united together. Its base or free edge contains the round ligament between its layers.

The round ligament (ligamentum teres) is a fibrous cord resulting from the obliteration of the umbilical vein. It ascends from the umbilicus in the free margin of the falciform ligament to the notch in the anterior border of the liver, from which it may be traced along the longitudinal fissure on the under surface of the liver; on the posterior surface it is continued as the obliterated ductus venosus as far back as the inferior vena cava. (Gray.)

Thus it is seen that in the round ligament of the

liver we have a natural tractor as evinced by an operation in the upper abdomen and traction on this ligament causes some motion and displacement of the liver bulk so that in the presence of any inflammatory or traumatic conditions in this region this will cause pain at the affected site.

To elicit this sign the patient's shoulders should be elevated on pillows to relax the recti muscles, the examiner stands on the patient's right and facing him, the right index finger is hooked in the umbilicus, and with gentle traction forces the umbilicus *downward in the direction of the pubis*. Should the umbilicus be too shallow the finger may be reinforced by a damp cloth or a strip of adhesive plaster with the adhesive surface outward. The mechanism involved in this maneuver is to put the round ligament on the stretch, causing some traction on the liver and slightly rotating it downward and forward.

This sign has proven positive in some cases of acute cholecystitis, cholelithiasis, abscesses of the liver associated with suppurative pylephlebitis, and in a case of traumatic laceration of the right coronary ligament. From a theoretical standpoint it may be of value in cases of subphrenic abscess, but fortunately or unfortunately no cases have presented themselves to us lately on which to attempt to demonstrate it.

Of course this sign is not claimed to be pathognomonic of any condition or conditions and the fact that it may prove negative in any of the conditions mentioned has no absolute significance; but its ease of application may serve at the bedside in a goodly number of cases to accentuate correlated signs and symptoms.

HYPNOTIC DRUG POISONING.

By A. S. TEPPER, M.D.,

Far Rockaway, New York.

Despite the general use of hypnotics in medicine, very few cases of poisoning are recorded. In the last three months, two cases have come under my observation. In the first case, that of a child, 40 grains of veronal were taken at one dose, while in the second case, that of an adult, approximately 100 grains of monobromated camphor, in the course of 24 hours, were taken.

Case I.—A. D., male, white, æt. 7, usual diseases of childhood, meningitis (epidemic) at age of 4; recovery good; no sequelæ; well built, well nourished; physical examination negative. On February 12, about 7 P. M. I received a call to the house. On arrival I found mother immersing the child in a tub of cold water, in an attempt to arouse him, with no success. The following developed from the history. Just before lunch, about 12 noon, the child complained of being sleepy so the mother advised him to go to bed. At about 6 P. M. the mother went to the bedroom to arouse the child but was unable to do so. She then placed him in the cold tub, but finding no results, called in the physician.

The child was in a deep coma, respirations, 30, very light and similar to natural sleep; pulse 102, and very shallow. Drastic measures to arouse him proved of no avail—pulling the hair at the back of the neck; pressing on the supraorbital nerve, and sitting him up and slapping him. At this time the father arrived and remarked that his box of capsules were missing—(veronal grains 10 in each capsule). The box was then found and four capsules were missing. A cup of black coffee was prepared and this administered, teaspoonful at a time by mouth. The patient would swallow it, grunt, and then return to unconsciousness. At 9 P. M. an enema of two cups of coffee and a hypodermic injection of strychnine sulphate gr. 1/60 were given, as the pulse had gone to 140, was fluttering, and very feeble. The patient responded to this, opened his eyes, cried out,and became very restless, throwing off the bed clothes and swinging his arms and legs. After about 10 minutes he again became unconscious. The family were instructed to watch him during the night and the next morning, by slapping him, he could be aroused for a moment but he would then relapse into sleep again. Milk and broth were administered by mouth for two days, after which his periods of consciousness became longer until at the end of five days he was fully conscious, none the worse for his experience. It later developed that the patient and his brother were playing "doctor" the brother being the doctor, who gave him four capsules of veronal 10 gr. each. At the present time the patient shows no ill effects, going to school daily and in perfect condition.

Case II.—J. H., æt. 19; drug clerk; previous history negative, neurotic temperament. On March 24 he presented himself at office suffering with an acute balanoposthitis. This was treated and on April 3 a circumcision was performed under general anesthesia. On April 4 he was told to take monobromated camphor, gr. 5 every 4 hours to prevent erection. Instead of following instructions he took the drug at very frequent intervals, most probably taking in all 100 grains in the course of 24 hours. On April 5, at 9 P. M., I received a hurry call to the drug store where the patient was employed. The history developed that the patient was standing behind the counter talking to one of the other clerks, when suddenly he cried out, threw his arms up, and fell backward on the floor striking on his head. He was then carried into a rear room and placed on the floor where the physician found him. He was markedly cyanosed, pulse slow and bounding and respirations labored. He showed typical signs of brain irritation, kicking his feet about, throwing his arms around, striking the floor with his fists, and crying out. The attack resembled epilepsy very much, but there was no history of any previous attack. After about ten minutes he became more quiet. He could be aroused by shaking, when he would look around, ask where he was, and then fall back again. He was allowed to remain there for half an hour, when he was lifted and feeling a little better he was taken home, walking three blocks. He was put to bed where he again became unconscious but very restless; this continued for 24 hours after which he felt better except for a violent headache and extreme drowsiness. He was kept in bed for 48 hours and then allowed to get up. At present date he shows nothing unusual.

ARCH SUPPORTERS FOR FALLEN ARCHES.

By MAX STRUNSKY, M.D.,

New York.

If a law prohibiting the sale of plates for fallen arches were passed and the sale restricted to the making of plates on the prescriptions of physicians with experience in foot trouble, it would be a boon to suffering mankind. The present fad of the public of prescribing arches for itself when there is trouble with feet has led to untold suffering, and even to irreparable damage to tissue, invalidism, crippling, amputation of limb, paralysis, and premature death. This is not an hysterical statement and one can easily see in our clinical material the evil of this self-prescribing habit and how it leads relentlessly to the above catastrophes. When a patient buys and wears arches he feels naturally that the trouble which causes the pain in his feet is being cured. Often he gives himself plenty of time for the arches to "work." Thus delays occur before a physician is consulted with the result that constitutional diseases perhaps of the most serious order of which the pain in the feet is but a symptom, have progressed untreated and undetected to the point where one of the above catastrophes may occur.

Let me give an example. Take for instance the most common type of patient who eventually comes to us for the relief of foot trouble. In his shoes he wears arches, and he tells us that he has already

worn several different makes. His face is clouded and puzzled, not seeming to understand why his feet still ache. An examination shows that he has an infectious arthritis of the metatarsophalangeal joints or midtarsal joints, and often even larger joints are involved. In his system somewhere there is a distinct focus of infection, either a faulty bridge in his mouth, under which oozes pus, or there is a sensitive tooth under a crown, or crypts in the tonsils, etc. Of course the scientific link between focal infection and joint diseases has not yet been completely forged. Yet clinically we know that treating focal infection has given better results in inflamed joints than all the previous methods for "rheumatism" that have ever been used. Also, we now know that to carry a pus cavity in the system is not as harmless as was formerly thought, but is fraught with danger. In the long run it breaks down the patient's resistance, causing metastasis, and the parasite often has been proven to change its strain and to set up an endocarditis or a pneumonia. It is a question worth while pondering, how often patients' lives have been lost through disease while they were waiting for their arch supporters to cure the pain in their feet? If, however, they had gone to a physician and the focus of infection had been discovered and treated, might not the premature death perhaps have been prevented?

Here is another example: A patient for months has experimented with various kinds of plates. The pain in his feet is terrible, so that he has forgotten all about the still persistent "morning drop." It is so frequent an occurrence to find patients with Neisser infection of the feet and spurs of the feet due to the same cause, wearing plates for a long time, often for years, while their focal infection was left undetected and untreated, that we are almost surprised when this is not the case.

The diagnosis of foot trouble is a difficult art. For how otherwise can one account for the fact that patients frequently come to us carrying plates which, from a mechanical standpoint, are well made and perfectly fitting and were prescribed by even well known physicians, who on examination reveal Romberg's sign, the Argyll-Robertson pupil, etc. Lately a patient with endarteritis obliterans came to our notice who had a Wassermann 4 plus reaction and whose limb was finally amputated for gangrene, and this man had been treated for eight months with plates! If it were not for the fictitious frequency of flat feet as a cause of painful feet, the true nature in the above cases would have had a greater chance of recognition, and different results would have undoubtedly ensued from prompt treatment. While all this time the patients were being treated with plates, the *Treponema pallidum* in the one case was eating away the true motor cells in the spinal cord, or causing in the other thickening and thrombosis in the arteries of the leg.

236 West Seventieth Street.

The Sex Distribution in Rickets. — J. Priestly concludes from the analysis of school statistics that rickets is more prevalent among boys than girls, the ratio being 27.3 to 16.3; and that this disease must be included with rheumatism, pulmonary tuberculosis, all the graver nervous affections, and some other disorders, as diseases the incidence of which is influenced to a considerable degree by sex.—*British Journal of Children's Diseases.*

Medicolegal Notes.

Licensing of Non-Drug-Giving Physicians. — The North Carolina Supreme Court holds that under Laws 1907, Chap. 764, as amended by Laws 1913, Chap. 92, providing for the examination and licensing of non-drug-giving physicians, and making it a misdemeanor for an osteopath or other non-drug-giving practitioner to practise without a license, one practising chiropractic and also a practitioner of suggesto-therapy must obtain a license.—State vs. Siler, North Carolina Supreme Court, 84 S. E. 1015.

Blood Stains on Accused's Clothing — Preliminary Proof.—To render blood-stained clothing admissible in evidence in homicide cases its identity must be established, and it must appear that it had not been interfered with either purposely or otherwise. In other words, to render such evidence admissible there should be preliminary proof that the clothing was worn by the accused at the time of the tragedy and that there has been no change in its condition between the date of the tragedy and the time of the test of the blood stains or the time when the clothing is admitted in evidence. It is not essential that this preliminary proof be made by positive or direct evidence, but it may be shown, as any other controverted fact, by evidence circumstantial in its nature. However, the proof should be such that the inference may be fairly drawn that the clothing was worn at the time and that the blood stains were there received. Tests for blood stains on the clothing of an accused charged with murder were not made until six months after the murder, and the evidence did not show the condition of the clothing during the interval or that it had not been interfered with, but showed that it had passed through the hands of several persons during the interval. It was held to be error to admit in evidence the clothing and the testimony of a physician that on making a scientific test he had found human blood stains thereon.—State vs. Ilgenfritz, Missouri Supreme Court, 173 S. W. 1041.

Malpractice in Reducing Fracture of Collar Bone—Sufficiency of Evidence.—In an action against a surgeon for negligence in reducing a fracture of the plaintiff's collar bone the negligence charged was that the defendant failed to use ordinary care in treating the fracture by carelessly and negligently bandaging and placing the ends of the bone in such position that they overlapped by more than an inch and causing them to be held in that position until they adhered and solidified. The evidence showed that the fragments of the broken limb had not healed in a proper position, which had caused a deformity and condition which rendered the plaintiff a cripple; but counsel for the defendant contended that there was no testimony to establish that this condition was the result of negligence on the part of the defendant.

In the absence of a special contract the law implies that a surgeon employed to treat an injury contracts with his patient that he will exercise reasonable and ordinary care to accomplish the purpose for which he is employed. He does not warrant a cure and is not responsible for want of success unless it results from a failure to exercise ordinary care, or from want of ordinary skill. The failure to exercise ordinary care in treating a fracture is not established by proof of the result alone but must be shown by other evidence. Other evidence than the condition of the plaintiff, bearing on the question of negligence in treating the fracture, was introduced.

Several surgeons testified that the position of the fragments ought to have been discovered by the defendant while treating the plaintiff, that an examination would have disclosed the overlapping, and that the position of the shoulder indicated that the fracture was not healing in the proper position. The plaintiff also testified that he complained to the defendant, about a month after the bone was set, that it hurt him to breathe, which, from the testimony of the physicians, must have been caused by the clavicle not being in a proper position. So that there was substantial testimony from which to deduce one of two conclusions: either the defendant did not place the fragments in proper place in the first instance, or, if he did, he failed to exercise ordinary care from time to time to ascertain whether they remained in place and in keeping them in proper position. A verdict for the plaintiff was sustained on appeal. — Craghead vs. McCullough, Colorado Supreme Court, 146 Pac. 235.

MATERNAL METABOLISM AND MONSTROUS DEVELOPMENT IN THE OFFSPRING.

EXPERIMENTAL biology has helped a good deal in the solution of many of the problems in human pathology. One of the most promising fields of research is that dealing with the causation of defective and monstrous development in the offspring. Some of the factors in the production of atypical intrauterine growth have already been clearly established; for instance, the effects of traumatism, uterine malformations, and disease, amniotic bands, etc. F. P. Mall has assumed that the defective development of an embryo is the result of the faulty implantation of the ovum in the wall of the uterus, which occurrence is in turn caused by a diseased condition of this organ. Another theory is that which attributes the origin of monstrosities to chemical or toxic effects on the developing ovum. O. Hertwig produced spina bifida in amphibian embryos by subjecting the fertilized eggs to the action of 0.6 to 0.7 per cent. solutions of sodium chloride, and suggested that the influence of alcohol or toxins in the maternal blood may account for some instances of monstrosity in the human being. Féré, Stockard, and McClendon obtained one-eyed monsters by submitting developing eggs to the action of magnesium chloride, alcohol, ether, alkaloids, etc.

Many of the above facts are cited by E. I. Werber in prefacing the report of his own interesting experiments along this line in the *Bulletin of the Johns Hopkins Hospital*, June, 1915. At the Marine Biological Laboratory of Woods Hole, Mass., he performed a number of experiments on the fertilized eggs of the teleost fish *Fundulus heteroclitus*. The eggs were submitted in the early cleavage stages to the action of solutions of a number of toxic substances known to be found in the urine of persons suffering from disturbances of metabolism. Only two of these substances, butyric acid and acetone, have so far given definite results. When fertilized fundulus eggs were exposed to the action of a 1/12 to 1/14 gram-molecular solution of butyric acid in sea water for about 15 to 20 hours and then transferred to pure sea water, a very large number of them gave rise to monsters. The same occurred with the use of a gram-molecular solution of acetone, 20 to 50 c.c., of which were added to 50 c.c. of sea water. The relative number of monsters increased with the strength of the solution up to 40 c.c. of acetone and decreased in solutions still stronger, which caused the death rate of the eggs to increase.

Among the monstrosities experimentally produced in the above manner there occurred very abundantly cyclopia, asymmetric monophthalmia, and microphthalmia. Coloboma, total blindness, the presence of lenses only, or the presence of supernumerary lenses were quite frequently found. Anterior half-embryos were also produced. Some embryos had enormously swollen ear vesicles, others were hydrocephalic, and others showed various deformities of the heart and blood-vessels. There was only a slight tendency to the production of twins. On the basis of the above findings the suggestion is made that many of the monstrosities found in nature are the result of the action of substances, such as acetone and butyric acid, the products of a disturbed or pathological metabolism. It is quite possible also that many congenital defects of the sense organs, of the central nervous system, etc., are to be attributed to the same cause. These defects may not be manifest morphologically, but may consist in slight chemical alterations, the effects of which may be latent until some advanced period of life.

This conception of intrauterine poisoning of the developing ovum is one of profound significance in pathology. The problem readily lends itself to experimental investigation. The results promise to elucidate many of the obscure metabolic disorders, such as diabetes, arthritism, etc. Many instances of so-called inherited disease may eventually be shown to be the result of intrauterine intoxication.

PYLEPHLEBITIS COMPLICATING APPENDICITIS.

THAT this complication of appendicitis has not received the attention that it merits has recently been pointed out by Babler (*Annals of Surgery*, May, 1915). He states that pylephlebitis occurs with greater frequency than we have appreciated; that many of the cases recover without our having recognized the presence of this complication; and that many patients die without our having correctly interpreted the clinical picture. In 1903 Gerster reported 1,189 operative cases of appendicitis, in 9 of which pylephlebitis was present, while in 1905 Munro reported 15 cases of undoubted portal infection; Körte cites 16 cases, and others have reported smaller numbers.

The abscesses in the liver are practically always multiple, vary greatly in size, and the right lobe is more frequently involved than the left. The most frequent clinical manifestations of multiple abscesses of the liver complicating appendicitis are repeated chilly sensations or distinct chills, followed by very high temperature and profuse sweating and associated with the presence of urobilin in the urine and persistent icterus. There is also pain in the hepatic region.

In a typical case of multiple abscesses of the liver complicating appendicitis the diagnosis should not be difficult. In any given case the diagnosis must rest on (1) the history showing that the ap-

pendix was the primary seat of trouble; (2) the shifting of the symptoms from the appendix to the hepatic region; (3) the progressive increase in the severity and character of the symptoms; (4) the repeated chills followed by high pulse rate and marked elevation of body temperature; (5) the jaundice; (6) the persistent pain in the hepatic region; (7) the urinary and blood findings; (8) the change of liver dulness; (9) the picture of marked toxemia, and (10) the absence of the signs and manifestation of extensive peritonitis. With Munro, Babler lays emphasis on the fact that the most important clue in making a diagnosis is the recognition of the causative appendicitis, and he says that the fact that an appendicitis patient is suffering from repeated chills followed by high temperature and profuse sweating indicates clearly the gravity of the situation and points to a septic condition somewhere, and when the physical findings point to the liver it is time to consider immediate exploration.

The prognosis with this complication is necessarily grave and depends on: (1) the size, multiplicity, and location of the abscesses, as well as their accessibility from a surgical standpoint, (2) the time of their discovery, and (3) the general condition of the patient together with the character and time of the treatment. Regarding treatment Babler says that the appendix should be removed, the infected lymphatics leading from the appendix to the liver should be incised and drained, and the liver should be exposed and the abscesses located and drained.

This is one of the complications of a neglected or medically treated appendicitis, and it is a very dangerous complication (Babler reports three more cases with three deaths). Acute appendicitis usually demands immediate operation while infection is limited to the appendix, for then the operation is simple and the mortality is practically nil.

PSEUDOREACTIONS WITH THE SCHICK TEST.

Numerous articles during the past two years have testified to the value of the Schick toxin test for immunity in diphtheria and the various investigators have exhibited a rather remarkable agreement in the essentials of the technique and interpretation of the reaction. The one source of trouble, one not infrequently present with other skin reactions, has been the tendency of some individuals under certain conditions to develop a condition of hypersensitiveness of the skin, the so-called "Umstimmung." In such patients the skin reacts excessively to the mere trauma which necessarily accompanies the application of the test and it may be extremely difficult to distinguish between a positive and a negative reaction.

Kolmer and Moshage (*Jour. Am. Med. Assn.*, 1915, lxv, 144) have investigated this phenomenon and presented a number of conclusions which should tend to clear up the confusion surrounding it and measurably to increase the value of the test. They found that this hypersensitiveness was most evident in patients in the various stages of scarlet fever, and more evident in those with measles than in normal individuals. At the end of eighteen or twenty-four hours they were often unable to distinguish between the pseudoreaction and the true, though the former was usually of less extent. After this time, however, the great majority of the false reactions subsided while the true toxin reactions persisted for several days and left a pigmented area and well-defined scaling of the epidermis. Increase in the amount of fluid injected produced a slightly larger number of pseudoreactions while increase in the concentration of the toxin had much the same influence. They therefore advise the use of a highly potent toxin and a minimum amount of fluid. Schick used a toxin having a minimum lethal dose of 0.005 c.c. and injected one-fiftieth of this amount so diluted as to be contained in 0.1 cc. The percentage of tricresol should not be more than 0.25. "When time permits it is better to read the reactions after forty-eight than after twenty-four hours, although in the presence of exposure to diphtheria it may be advisable and necessary to inspect the reactions and immunize nonimmune or positively reacting persons at the end of twenty-four hours." The use of a control fluid, a dilution of bouillon of 1:10 or 1:100, will aid materially in the detection of these pseudoreactions and is especially important when testing patients suffering with scarlet fever or measles.

The error introduced by these false reactions is, however, on the safe side, for a positive reaction indicates that the patient is not immune and should receive a dose of ontitoxin and, as the authors say, it is probably better in the presence of exposure to diphtheria to err on the side of giving antitoxin to an immune person than to withhold it from a nonimmune.

Tubercle Bacilli in the Gastric Contents

One of the routine pocedures in the endeavor to establish the diagnosis of pulmonary tuberculosis is, of course, the examination of the sputum for tubercle bacilli. Such an examination is naturally impossible in small children who do not cough up their sputum, and in those early cases in which the sputum is absent or inappreciable in amount. The examination is unsatisfactory when the patient is too stupid to bring a suitable specimen of sputum or produces a mixture of saliva and food remnants in an attempt to deceive the physician. In those instances in which the patient is unconscious it is often impossible to obtain any sputum. In all of these cases the bulk of the sputum is swallowed, and it is but reasonable to suppose that a satisfactory examination may be had if the material is recovered from the stomach. Levy and Kantor (*Archives of Diagnosis*, 1915, viii, 154) have been able to demonstrate the tubercle bacillus in two instances in the material extracted from the stomach. The tubercle bacillus is very resistant to the action of digestive ferments, and there is no good reason to doubt the possibility of its recognition even after a stay in the stomach of several hours. The authors recommend that the material be extracted in the morning before the taking of any food, with the aid of a suction bulb. This

method would seem to be especially well adapted for use in infants in whom the time-honored method of tickling the throat with a feather is often ineffectual.

Polyneuritis of Rubber Vulcanizers.

Among occupation neuroses, one not often heard of is polyneuritis due to bisulphide of carbon in connection with vulcanizing rubber. There is in reality more to this affection than a toxic neuritis, for evidences of general intoxication coexists to some extent. Mild cases of this affection are not so rare, but cases of the severest type appear to be very infrequent. At a clinical session of the Leipzig Medical Society last March (*Muenchener medizinische Wochenschrift*, May 4), Schröder described a case of severe type. The patient had been a vulcanizer for six years before symptoms of poisoning appeared. Numerous sensory disorders were present —paresthesiæ and lightning pains in the legs. Headache seems to have been the earliest symptom, and was associated later with vertigo, excitability, and failing memory. The patient had lost much weight, was anemic, with swollen feet and shedding of hair. Motor troubles were numerous, including pareses and ataxia of both upper and lower extremities and there was also muscular atrophy in the hands. Locomotor ataxia was closely simulated, the Romberg sign being positive, but the patella reflex was heightened and the pupils were normal. The sensory disturbances had the hysterical distribution. Direct evidence of neuritis was easily obtained (tenderness on pressure, etc.). Some improvement has followed cessation of occupation.

Paravaccine.

That keloid should develop occasionally in vaccine cicatrices has never seemed other than a natural phenomenon, since this condition may develop in the predisposed in any recent cutaneous wound and hypertrophic cicatrices are common enough in the absence of predisposition. There is, however, another condition which has doubtless been included under vaccination keloid, termed by von Pirquet paravaccine. At a meeting last March of the Royal Imperial Medical Society of Vienna (*Berliner klinische Wochenschrift*, May 3) this author presented two cases in which vaccination apparently did not take. Instead small nodules developed having a raspberry color. They increased very slowly in size and presented a delicate areola. Vesiculation never occurred, and the lesions underwent involution very slowly. They were entirely harmless and were significant only because they might be regarded falsely as a successful take. Von Pirquet believes that paravaccine is more frequent now than in former years. It should not occur if vaccination is properly performed. The incisions should be ample and the thick portion of the vaccine well rubbed in. In these cases the failure to take raises the question of impure lymph as well as poor technique.

News of the Week.

Committee of American Physicians for the Aid of the Belgian Profession.—Dr. F. F. Simpson, treasurer, 7048 Jenkins Arcade Building, Pittsburgh, Pa., reports the receipt of the following contributions for the week ending July 17, 1915:

Muskegon Oceana Medical Society, Muskegon, Mich	$25.00
Dr. Robert F. Taylor, Philadelphia, Pa.	5.00
Dr. Francis Reder, St. Louis, Mo.	10.00
Dr. Charles D. Lockwood, Pasadena, Cal.	5.00
Dr. J. W. Ellenberger, Harrisburg, Pa.	5.00
Dr. Charles N. Dowd, New York, N. Y.	25.00
Receipts for the week ending July 17	$75.00
Previously reported receipts	7,625.84
Total receipts	$7,700.84

Health of the Canal Zone.—Dr. William F. Mason, chief health officer, reports that during May, among a population of 34,560 in the Panama Canal Zone, there was a total of 36 deaths; of these 30 deaths were from disease, giving a rate of 10.41 per thousand, as compared with 5.71 for the preceding month and 12.93 for the corresponding month of last year. Of the total deaths from disease the percentage under 5 years was 60, compared with 69 during April. There were 44 births reported, giving a rate of 15.28 per thousand. Of these births 10 were of white and 34 of colored children. There were 12 deaths of children under 1 year of age, all of whom were colored. In Panama City, with a population of 60,373, there was a total of 132 deaths. Of these 127 deaths were from disease, giving a rate of 25.24 per thousand, as compared with 25.44 for the preceding month and 32.31 for the corresponding month of last year. Of the total deaths from disease the percentage under 5 years of age was 63, compared with 51 in April. In Colon, with a population of 29,331, among whom there were 47 deaths; of these, 44 deaths were from disease, giving a rate of 18.00, as compared with 19.64 for the preceding month and 30.25 for the corresponding month of last year. Of the total deaths from disease, the percentage under 5 years was 37, compared with 52 in April.

Epidemic of Measles in New York Declining.—According to figures compiled by the Bureau of Records of the Department of Health, the outbreak of measles which has prevailed in New York City for the past few weeks has passed its height and is now declining. The decline is clearly reflected in the death rate 11.02 per 1,000 of population as compared with 11.24 for the corresponding week of 1914.

Pellagra in Texas.—Warnings to guard against pellagra, now declared by the State Board of Health to be prevalent in Southeast Texas, have been sent to all the local health officers in that part of the State.

Cholera in Austria.—It is reported that cholera is prevailing to an alarming extent in many districts in Austria, in some parts of which it has been declared epidemic. In the four days from July 8 to July 12, 723 new cases of the disease were reported in Austria, and in Hungary there were 543 cases in one week.

Typhus in Serbia Under Control.—Dispatches from London credit Sir Thomas Lipton, who recently returned there from his second trip to Serbia, with the statement that the work being done by the American physicians is marvelous. While the French and British medical corps are doing splendid work, he said, the credit for sanitation must go to the Americans, who, "as usual, excel in organization and preventive measures." At the height of the typhus epidemic, Sir Thomas said, there were upward of 300,000 cases, and the country was overridden with vermin. Owing to the sanitation reforms inaugurated by the Americans the plague of lice has been overcome and the typhus epidemic is well in hand.

Sir Felix Semon, the well-known laryngologist

of London recently wrote to the *Times* in reference to the *Lusitania* murders, expressing his righteous indignation at "Germany's barbarous warfare." In reply the Berlin Laryngological Society dropped his name from its list of honorary members and the *Internationales Centralblatt*, which he had founded, removed his name from the title page, which, of course, destroyed the journal's claim to be international in character. When the German professors come to they will wonder what made them so irrational and so unable to dissociate science from politics.

No Coroners for New York City.—Last winter the Legislature passed a law abolishing the office of coroner in this city, but the friends of the system have been trying to nullify this action by having the office included among those in the Constitution which the Legislature cannot disturb. The committee having this amendment in charge decided, however, by a vote of 9 to 4 to report it to the Constitutional Convention adversely.

Street Accidents in New York City.—Figures prepared by the Bureau of Records of the Department of Health show that during June, 1915, 34 persons were killed upon the streets of New York City by automobiles, an increase of 70 per cent. over the number of similar accidents that occurred during June, 1914. This increase, the report of the Health Commissioner states, is not at all exceptional; it is, on the contrary, only a reflection of the steady increase in this class of accidents that has been going on for several years. During the first six months of 1915, 152 lives were sacrificed. A conservative estimate is that one person in ten injured dies. Assuming this ratio to have held good in this city during the six months of 1915, there were 1,520 persons injured by automobiles. The remedy for this needless sacrifice of life, the department holds, is the adoption of a State law or a city ordinance which will compel those who desire to operate motor vehicles on the streets of the city to submit to an adequate test of fitness as a condition precedent to the obtainment of a license or permit. Under the present Highways law of the State of New York, any owner or any member of the family of an owner is permitted to drive a motorcar. The question of mental or physical capacity does not enter.

A Symposium on Rheumatism.—A special number of *American Medicine* dealing with rheumatism was published as the June issue. The twenty-nine contributors made up in their papers a very full and interesting symposium on the subject. Ten of those who contributed papers hailed from Great Britain, among them being Sir Dyce Duckworth, Sir Arbuthnot Lane, and Drs. Tanner Hewlett and F. G. Poynton. The contributions from American physicians and surgeons fitted in excellently with those of their British confrères and the entire number is a credit to American medical journalism. The issue can be profitably studied by one wishing to learn of the most recent views regarding that congeries of affections classed under the head of rheumatism, for the subject is discussed from all standpoints, special attention being paid to the question of treatment.

A Four-County Medical Meeting.—One of the largest medical meetings held in Western New York in recent years was the joint meeting held at Glen Iris, Letchworth Park, Yyoming County, by the medical societies of the counties of Allegany, Genesee, Livingston, and Wyoming on July 15. Over 300 guests were present. In addition to the members of the four societies there were others from Monroe, Erie, Ontario, Niagara, Cattaraugus, Steuben, Seneca, Schuyler, and Wayne counties. Dr. L. F. Bishop of New York City read a paper on Cardiovascular-Renal Disease, and Dr. William S. Bainbridge of New York City one on Chronic Intestinal Stasis. It was voted to make this joint meeting a permanent affair and to invite other counties in Western New York to join, the presidents and secretaries being delegated to make arrangements for a permanent organization.

State Medical Examinations.—At the recent State license examination in Ohio 160 candidates passed, only five being rejected.

In South Carolina the successful candidates in the examination held in June numbered 36.

At the June meeting of the Virginia State Board 127 recent graduates presented themselves for examination to obtain a license to practise medicine in that State.

Obituary Notes.—Dr. CHARLES UPHAM SHEPARD of Summerville, S. C., a graduate in medicine of the University of Göttingen, Germany, in 1867, died at his home on July 4, age 72 years. Dr. Shepard retired from the practice of medicine some years ago, and by his success in the growing of tea on his plantation, the Pinehurst Tea Farm at Summerville, won for himself the title of "Father of the Tea Industry." He was said to be the only person in America who had been able to grow tea for the market. This work had been watched with great interest by the Department of Agriculture.

Dr. JOSEPH REDFEARN of Marlboro, Mass., a graduate of the College of Physicians and Surgeons, New York, in 1873, and a member of the American Medical Association, the Massachusetts Medical Society, and the Middleboro District Medical Society, died at his home from apoplexy, after a short illness, on July 1, aged 65 years.

Dr. GEORGE W. STEPHENS, formerly of Montgomery City, Mo., a graduate of the St. Louis College of Physicians and Surgeons in 1883, died at the home of his daughter in St. Louis on June 24, aged 66 years.

Dr. BENJAMIN C. WOODBURY of Patten, N. H., formerly of Lewistown, Me., a graduate of the Homeopathic Medical College of Pennsylvania, Philadelphia, in 1866, died at St. Petersburg, Fla., on June 8, aged 78 years.

Dr. POWHATAN BLEDSOE of Hylas, Va., died at his home on June 26, aged 87 years.

Dr. EDWARD C. SCHOONMAKER of Mercedes, Tex., a graduate of the University of Minnesota Medical School, Minneapolis, in 1899, and a member of the American Medical Association, the State Medical Association of Texas, and the Hidalgo County Medical Society, died suddenly on July 4, aged 44 years.

Obituary.

FRANCIS DELAFIELD, M.D., L.L.D.

NEW YORK.

DR. FRANCIS DELAFIELD of New York, emeritus professor at the College of Physicians and Surgeons, New York, and consulting physician to the Roosevelt, Bellevue and St. Luke's Hospitals, died at the home of his sister in Darien, Conn., on July 17, aged 73 years.

The son of a physician, Dr. Edward Delafield, president of the College of Physicians and Surgeons, Francis Delafield was born in New York in 1841, and was graduated from Yale University in 1860 and from the College of Physicians and Surgeons in 1863, continuing his studies in London and Paris, and interesting himself especially in the study of pathological anatomy so that he soon became one of the most prominent workers in scientific medical research. In 1875 he was appointed adjunct professor of medicine at Columbia University (College of Physicians and Surgeons), and in 1882, on the retirement of Prof. Alonzo Clark, he became professor of pathology and the practice of medicine, holding this chair until 1901, when he also retired. In 1877 the Association of the Alumni of the College of Physicians and Surgeons organized a Pathological Laboratory on a plan suggested by Dr. Delafield, and he was made director, which office he held for four years, being then succeeded by Dr. T. Mitchell Prudden. Dr. Delafield at different times had served as pathologist to the Roosevelt Hospital, surgeon to the New York Eye and Ear Infirmary, and physician to several other hospitals. Besides his membership in many medical societies, including the New York State and County Medical Societies, the New York Pathological Society, of which he was one of the incorporators and president in 1875, the Association of American Physicians, of which he was the first president (1886), and the New York Academy of Medicine, he was a member of the Century Association and the Yale Club of New York.

Dr. Delafield's contributions to medical literature have been landmarks in scientific work. His first work, "A Handbook of Post-Mortem Examinations and Morbid Anatomy," was published in 1872; and in 1882 the "Studies in Pathological Anatomy" appeared. Delafield and Prudden's "Handbook of Pathological Anatomy and Histology," which was first issued in 1885, reached its fifth edition in 1897, after which Dr. Delafield retired as a collaborator.

R. H. M. DAWBARN, M.D.

NEW YORK.

Dr. Robert Hugh Makay Dawbarn of New York clinical professor of surgery in the Fordham University School of Medicine, New York, and emeritus professor of surgery in the New York Polyclinic Medical School, visiting surgeon to the City Hospital, and consulting surgeon to the New York Polyclinic, died at his home on July 18, aged 55 years.

Dr. Dawbarn was graduated from the College of Physicians and Surgeons, New York, in 1881, and in 1890 was appointed professor of surgery and anatomy at the New York Polyclinic Medical School, having previously served as instructor in minor surgery at the College of Physicians and Surgeons. He had served as visiting surgeon to the New York Hospital and consulting surgeon to the Greenwich Hospital, and was a member of the American Medical Association, the New York State and County Medical Societies, the New York Surgical Society, the American Association of Anatomists, the New York Academy of Medicine, the New York Society of Medical Jurisprudence, and the West End Medical Society. In 1902 the Philadelphia Academy of Surgery awarded to Dr. Dawbarn the Samuel D. Gross prize for the best original work on surgery during the previous six years.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

ALIMENTARY STASIS, CAVENDISH LECTURE—X-RAY LOCALIZATION, ROENTGEN SOCIETY—NATIONAL MEDICAL UNION—CASUALTIES AND HONORS IN WAR—HEALTH OF THE FORCES.

London, July 2, 1915.

The Cavendish lecture was delivered this day week by Prof. Arthur Keith, F. R. S., at the West London Hospital, his subject being "Alimentary Stasis"—not confining the term to stasis of the larger intestine, but extending it to include the canal throughout. Examining Auerbach's (mesenteric) plexus, he showed that at all parts of the canal it was a composite tissue, containing nerve cells, numerous fine nerve fibers, and an abundant third element—a form of branched cell, apparently intermediate between nerve and muscle, as if the plexus acted on them through the third element. Auerbach's tissue was specially abundant where movements commenced. Physiologists teach that every point in the canal has its own rhythm, being always in a state of rhythmical contraction and in the proximal part of the colon as well as in the duodenum, jejunum, and ileum the rhythm diminishes on to the end of each segment. Professor Keith looked upon the canal as made up of seven such segments or zones, just as the heart may be looked upon as consisting of two zones—auricle and ventricle. At the junction of the heart's two zones there may occur some interruption of rhythm, in which case there will follow back-pressure in the veins. The usual sites of stasis have been observed to be just such junctions—esophagus and stomach, stomach and duodenum, and this with jejunum; other instances are ileum with cecum, proximal with distal colon, and colon with rectum.

At the annual meeting of the Roentgen Society a paper was read on X-Ray Localization Methods by Captain Shaxby, R. A. M. C., deserving the attention of all called upon to determine the depth of foreign bodies; for ordinary methods do not often enable us to decide whether such a body is above or below a broad flat bone, such as the scapular. This contribution having been duly honored, a discussion was opened by Dr. Sidney Russ on the protection of *x*-ray operators from the dangers of *x*-ray screen examinations. It had been attempted to protect operators by enclosing the *x*-ray bulb in a box covered with an absorptive material, except in the path of the vertical rays used, and other devices had been resorted to. It must be difficult for those working with the rays to realize the enormous amount of radiation given off, and Dr. Russ mentioned in this respect that the methods of measuring the rays in use are rather gross methods. There is always some stray radiation to be detected—it leads to the air becoming highly ionized—and this effect is not influenced by ventilation. Perhaps more attention will soon be given to the atmosphere in which the radiologist works. Dr. Finzi showed experimentally that though the usual protective box cuts off most of the primary rays, the secondary ones must be considered as they might prove equally dangerous to the radiologists. Mr. Gardiner, F. C. S., told of his experiments as to secondary radiations given off by different materials. He thought any efficient method of estimating must

take account of the secondary rays. Dr. G. B. Batten considered *x*-ray protection of the greatest importance, while radiologists were at work many hours a day in military hospitals and in the absence of definite rules it was probable outfits supplied to the war office often fell short of the desirable. He advised that a committee of the society should lay down rules for *x*-ray protection for users and others—in fact, all brought in contact with the rays. His suggestion was adopted by the meeting and the council of the society have undertaken to carry it out.

The National Medical Union held its annual meeting on Saturday, when the chairman, Dr. Greenyer, congratulated his audience on the fact that sixty-three of the members were on active service, of whom two had just been mentioned in dispatches for gallant conduct in the field. Professor Russell of Edinburgh moved and Dr. Comber seconded a resolution expressing belief in the value of military training for young men of all classes. He said the union was ready to assist in the organization of the country's forces for a more vigorous conduct of the war and urged an immediate census of the adult population. He also took the chair at the annual dinner in the evening when he said, while not sympathizing with every part of the insurance act the union recognized certain bedrock principles, on which medical help should be provided for the most necessitous. Other speakers predicted a great increase in the number of members of the only body, said one, to maintain the traditional freedom of the profession and prevent its degradation to the level of commercialism.

Prof. F. Howard Marsh, F. R. C. S., died on the 26th ult., aged 76. He was consulting surgeon to St. Bartholomew's Hospital, member of the Council of the Royal College of Surgeons, president of the Clinical Society, and held many other important posts during his great surgical career. On the reestablishment of the professorship of surgery at Cambridge in 1903 he went there to take the duty and was made a Fellow of King's College. Four years later he succeeded the late Alexander Hill as master of Downing College. The funeral took place on Tuesday at Cambridge, when there was a large attendance of eminent persons representing the university and colleges, the senate corporation of the city, and the county; the sister university of Oxford, the Royal College of Surgeons, St. Bartholomew's Hospital (London), the National Health League, and other medical and scientific institutions were also represented.

The casualty list in this terrible war, issued from time to time, includes many names of military surgeons who have fallen from wounds or gas poisoning or maladies incidental to the contest. On the other hand, we have still longer lists of medical officers mentioned in dispatches, or awarded honors, compensations, pensions, or other marks of distinction earned in active service.

Sir. J. Williams has been made Honorary Fellow of the Royal Society of Medicine.

Sir A. P. Gould has been elected vice-chancellor of the University of London for 1915-16.

The Leconte prize, a highly esteemed French distinction, has been bestowed on Sir Almroth Wright.

The Victoria Cross has been conferred on Captain Scrimger of the Canadian Army Medical Service. Dr. Purves Stewart has been appointed consulting physician to the forces in the Mediterranean and has started on the service.

In reply to questions in Parliament it has been asserted that the health of the forces in the present war is not merely favorable in comparison with former campaigns, but nothing equal to it has ever been attained.

EXPERT MEDICAL TESTIMONY.

To the Editor of the Medical Record:

Sir:—I believe Judge Hendrick's statement in the Thaw case, as regards the opinions of experts for pay, will be supported by the majority of all-around practitioners of medicine. They look upon such cases from a broad and sane standpoint. They have seen in Thaw's act, not evidence of insanity, but simply of a disposition prone to crime, by reason of bad influences and moral delinquency. The State prison and an indeterminate sentence would be the right way to punish such a crime against society. Then length of the sentence should depend upon conduct in prison, but conviction must be *swift* and *sure* to obtain good results to the State and to the criminal. All criminal trials should be enlightened and helped with the knowledge of a general physician of large experience and unblemished character. The court should appoint such a one in every case. Politics or pecuniary reward should not be in any way a factor in such an appointment.

Beverley Robinson, M.D.

SODIUM CHLORIDE SOLUTION.

To the Editor of the Medical Record:

Sir:—There being so much use of Fischer's solution, which I believe is sodium chloride and sodium carbonate, it might interest you to know that in the *Medical Herald* of March, 1908, I published under the title, "The Soil for Pneumonia, or the Condition That Allows of the Pneumococcus to Lodge," the following:

℞ Sodium chloride, 60 grains.
Sodium carbonate, 12 grains.
Boiled water, 1 pint.
Honey or glucose, 7 grains.

Sig.: One pint by enteroclysis two or three times a day.

The above formula was published some years before Fischer published his.

1. The Use of Magnetism for Localizing Needles in the Tissues; with Report of Cases. G. H. Monks.
2. Pollen Therapy in Hay Fever. J. H. Goodale.
3. Leprosy and Its Relation to Massachusetts. J. A. Honeij.
4. The Relation of Leprosy to the Community. G. M. Katsainos.

1. Use of Magnetism for Locating Buried Needles.—G. H. Monks finds that this physical agent is of value in some cases even though an *x*-ray examination has been made. The method comprises the use of an electro-magnet or an ordinary magnet to magnetize the buried needle, and of an indicator consisting of a very fine magnetized needle suspended by a delicate silk thread. The method is of value in cases in which the needle fragment is large enough to receive and to retain a charge of magnetism sufficient to attract the indicator needle. Cases in which the needle fragment is near enough to the skin to be strongly magnetized,

and also near enough to attract the indicator needle; and cases in which, during the progress of an operation, the incision opens up the tissues in such a manner that the indicator needle may be brought very close to the foreign body.

2. **Pollen Therapy in Hay Fever.** — J. H. Goodale states that serobiological methods have shown the phylogenetic relationship of the different plant orders and families. The application of these discoveries to the treatment of hay fever by injection of plant proteins promises to assist in the selection of the specific material required for a given case. Definite reactions are elicited in hay fever by the pollen of the exciting plants when brought into contact with an abrasion of the skin. The intensity of these skin manifestations may be sensibly diminished by the repeated parenteral administration of the proteins in question. Coincident with the diminution in the skin reactions, there seems to occur an increased tolerance of the exposed mucous membranes to the pollens of the plants employed. Pollen therapy in hay fever may be regarded at the present time as a promising method of treatment, but its value and the permanence of its results remain to be definitely established.

3. **Leprosy in Relation to Massachusetts.** — J. A. Honij notes that leprosy is exceedingly prevalent in Mexico, Brazil, and Latin-America in general. Boston is building up a South American trade and booming Boston as a port of entry. The Panama Canal gives a more direct route to countries in which the disease is endemic. Russia believes that because she has acted as a sieve for the East in past generations, the disease is so prevalent there today. Germany claims she gets her cases from Russia, France from her colonies and her southern neighbors, Hawaii and other islands from China and Japan. In America there are a few states in which the disease is prevalent and a few others in which the disease is endemic. The author advocates a more tolerant and sensible attitude toward lepers; a greater familiarity with the disease; a more sympathetic and true interest on the part of the State in their cases and a less complete isolation; and the provision of a modern hospital and of modern buildings for the proper care and treatment of leprosy. In treatment much can be done, and reports of arrested cases are frequently made. The prevention of disfigurement, toxic febrile attacks, pain, and general discomfort is successful in a great many cases.

4. **Leprosy and the Community.** — G. M. Katsainos believes that leprosy is inherited, and that the microbe exists in the spermatozoa and ova at the time of conception. Contagiousness is also possible, for otherwise one could not explain the existence and development of the disease in certain times and places. Nevertheless transmission by contagion is only a rare exception, taking place in a way that escapes detection The analysis of a number of family histories of lepers shows no case of transmission from the husband to the wife or from the wife to the husband; no case of contagion between neighbors, however close their relations with a leper may have been; that no person related to a leper by any marriage ties, but not of the same blood, has been affected; and that even when a child is the suckling of a leper woman it remains unmolested, if not born of her.

10. A Surgical Course for Hospital Internes. A. E. Chace.

1. **Old Age and Longevity.** — H. M. Friedman reviews the biological, physical, and mental aspects of old age. He notes that brain workers live longer than muscle workers and that clergymen are the longest lived individuals. Women live longer than men in spite of the morbidity of childbearing. Marriage tends to favor longevity and so does religious life. Heredity is an important factor in senility and longevity.

2. **Vaccines in Diseases of Nose, Throat, and Ear.**— G. M. Coates notes that the use of vaccines for prophylactic immunization against acute rhinitis, or common acute colds, has come into quite general use and is often very effective. On account of the number of different organisms causing these attacks, a mixed stock vaccine should be used. In suppurations of the nasal accessory sinuses vaccine therapy does not give permanent relief until adequate drainage has been established. Recurrent furunculosis about the alæ nasi and close to the alar cartilages are usually caused by one of the staphylococcus group, probably the albus most frequently, and yield in a most satisfactory manner to vaccine treatment. Practically all middle ear diseases have their origin in the nose and throat. If one can abate the catarrhal condition of the nose and epipharynx by the use of vaccines, one can feel some degree of assurance that the benefit will extend to the tube and tympanum. This is also true of the acute cases, but then one can usually take care of these by other means and in about the same time. For acute cases which fail to respond to ordinary measures and tend to become subacute and chronic, the use of vaccines produces good results in a short time. Marked success with vaccines in chronic suppurative otitis media was first obtained by Nagle, of Boston, who reported some seventy cases of long duration, in all but a few of which dry ears were obtained by the use of autogenous vaccines.

10. **A Surgical Course for Hospital Internes.**—A. E. Chace advocates the use of written regulations which should specify the hours of duty and the lines of authority; a definite schedule of the hospital practice in each department; and the ideals of scientific character at which the interne should aim, and the methods planned to attain them. The internship should be planned to stimulate scientific character. There are four elements of this to be developed: (1) *The attitude*, which compels one to surround each statement with proof before making it. Conscientious history taking and physical examinations, the laboratory, the operating room, and the autopsy, followed by well planned discussions of the cases, will soon convince the interne of the futility of snap diagnoses and premature statements of therapeutic efficacy. (2) *The habit* of systematic work; the planning of the best use of method and time toward efficient treatment. (3) *The energy* to review constantly the theory of practice in its relation to each concrete instance; and to practise under supervision upon the lower animals that manual dexterity which is essential to successful surgery. (4) *The ambition* to originate and to study in new fields; to prepare papers of scientific value and with some degree of rhetorical merit.

5. **Chronic Pancreatitis.** — By M. Einhorn. (See MEDICAL RECORD, June 26, 1915, page 1090.)

10. **Surgical Measures in Apoplexy.**—C. M. Remsen states that while it may appear radical to advocate operative procedures in cerebral hemorrhage there are two positive operative indications, namely, to relieve pressure of the clot and remove it if possible, and to relieve the brain from the secondary changes. A case is reported in which there was manifest an increased intracerebral pressure and in which an operation for decompression was made six days after the beginning of the attack. The brain was edematous and tended to project through the opening. The cerebral lateral fissure was demonstrated and posteriorly there was found a clot about the size of a golf ball, suggesting a lenticular hemorrhage which had worked out through the surface of the insula. The patient recovered.

12. **Acute Articular Synovitis of Nasopharyngeal Origin.**—W. Sohier Bryant reported the case of a young man suffering from a severe type of acute multiple synovitis affecting the knees and hips. The pharynx was red and there was nasal obstruction from a deflected septum. There was a large, soft adenoid, bleeding freely, but there were no subjective symptoms in the throat. The treatment began with postnasal applications of hydrogen peroxide through the nose, followed by a 10 per cent. solution of silver nitrate and an antiseptic nasal douche. The patient reported the following day that he felt relieved within half an hour after the treatment, and he was able to walk without crutch or cane and could sit down normally. His general appearance was no longer that of a serious invalid. Palpation detected scarcely any fluid in the knee. A saturated solution of ferric ammonium sulphate and menthol and eucalyptol was applied. On the fifth day all pain was gone and he felt much better and on the twenty-third day, after eleven treatments, there were no signs left of the arthritis.

July 3, 1915.

1. Trypanosomes Causing Disease in Man and Domestic Animals in Central Africa. Sir David Bruce.
2. The Right-sided Murmurs of Mitral Stenosis: Their Bearing on the Course of the Disease. Sir James F. Goodhart.
3. A Case of Congenital Hemihypertrophy. J. M. Fortescue-Brickdale.
4. Leprosy and Kedrowsky's Bacillus. H. Fraser and W. Fletcher.

1. **Trypanosomes.**—By Sir David Bruce. (See page 159.)

2. **The Right-Sided Murmurs of Mitral Stenosis.**—Sir James F. Goodhart states that there occurs in the later stages of mitral stenosis a regurgitant murmur over the right ventricle, and, as the author believes, at the tricuspid orifice, as a result of hypertrophy and dilatation of the right side. These changes may be so extreme that the right ventricle comes to occupy the place of, and thus to simulate, the left ventricle at the surface, and therefore to get at the left it is necessary to go round to the inferior angle of the scapula. Further, not only is the ventricle dilated but the pulmonary artery also, and the sigmoid valves are more or less incompetent and then there is generated a peculiar diastolic murmur at the orifice of the pulmonary artery that often has something in it of the quality of a venous murmur; it is long and sustained and sometimes musical. This murmur is quite distinct from the diastolic murmur that is supposed to be a long or early presystolic bruit. Among the notes of eighty-four cases of mitral stenosis the author finds one or other of these murmurs to be present in seventeen of them—the tricuspid murmur alone in seven; the pulmonary artery diastolic alone in six, and the two in company in four others. It may be said that if the quasi-mitral murmur be tricuspid, as the author maintains, the regurgitation would necessarily produce a reflux in the veins and appear as a pulsation in the neck, with other evidences of backward pressure, but it is a fact that in some of these cases there may be no such pulsation. The outlook in mitral stenosis is in most cases good for a number of years. As regards treatment the author believes that digitalis often does harm in mitral stenosis and that convallaria is as a rule more useful. Opium is often better still, by steadying the heart's action, and perhaps better than all in bad cases come leeches or venesection. Diet also needs consideration. Many of the patients are comfortable only when the meals are of the smallest. A patient suffering from mitral stenosis should never be laid up if it can be avoided, for if once he takes to the recumbent posture he is probably in for a slow decline of a very distressing kind.

3. **Congenital Hemihypertrophy.** — J. M. Fortescue-Brickdale reports the case of a male infant nine months of age in whom several months after birth the whole of the right side of the body was noticed to be larger than the left. The condition was recognized as one of congenital hemihypertrophy, of which there are the following groups: (1) Congenital elephantiasis or trophedema; (2) simple congenital hypertrophy of one or more limbs or of one side of the body ("true" or "false"); (3) intermediate cases, in which there is some general hypertrophy of a segment of the body and also a congenital tumor of a special tissue, and (4) congenital tumors involving a limb. The case described falls into the second group, the main characteristics of which may be summarized as follows: The condition is congenital and may involve a large or small area of the body, from a few digits to the whole of one side. The hypertrophy involves all tissues, but is more marked in the soft structures than in the bones, and thus usually affects the girth more than the length of the limbs. In one remarkable case reported by Reissmann the right side of the body and the left side of the head were involved, while in Ballance's case there was hemihypertrophy of the left side of the face with enlargement of the second and third toes of the left foot, and the third and fourth of the right. The boy was also said to be "rather simple." In Friedrich's case the opposite arm and leg were involved. The appendages of the skin, nails and hair, may or may not be involved; and in some instances the temperature on the affected side is higher. The right side is said to be more frequently enlarged

than the left and the lower extremity than the upper. Males are more frequently affected than females, and there is very seldom any family history of other congenital deformities, though occasionally a neurosis has existed in the parents. Thus, in Hornstein's case the mother was insane, and in that of Adams the father was dissolute. In one instance cited by Leblanc several members of a family exhibited congenital hypertrophy of the left hand.

5. A Case of Concealed Accidental Hemorrhage: Spontaneous Delivery: Recovery. R. B. Johnston.
6. Technique of Analgesia in Intranasal Surgery. W. Wilson.

1. Trypanosomes.—Sir David Bruce, in discussing the geographical distribution of these parasites, states that they are found in most parts of the world—from South America through Africa,. Southern Europe and Persia to India, Burma, China, and the Philippines. In Africa there is a broad equatorial band, representing the trypanosome diseases carried by tsetse flies. It shows the distribution of *Trypanosoma gambiense*, the cause of the ordinary or Congo sleeping sickness, and of *Trypansoma brucei*, the cause of nagana in animals and the Rhodesian and Nyasaland form of sleeping sickness or trypanosome disease in man. Further north out of the tsetse fly region there is *Trypanosoma equiperdum*, the cause of dourine, which is widely distributed in Europe. The area of *Trypanosoma evansi* or surra spreads out of Africa along the camel caravan routes into India and China.

3. Excision of Damaged Tissues in Treatment of Projectile Wounds.—E. T. C. Milligan advocates the extirpation of the devitalized tissues in the early treatment of projectile wounds. Under local or general anesthesia the wound of the skin is boldly cut out with a sharp scalpel. It should be so completely removed that a clean healthy incised wound replaces the contused and infected wound made by the projectile. There should be nothing of the old wound remaining. The wound of the superficial and deep fascia and of the muscle is dealt with in the same fashion. The removal of loose and fixed bits of obvious foreign and dead matter is, of course, essential. Ample exposure and drainage of the wound is necessary, and those wounds which are too extensive after the above treatment to retain a drainage tube do better than those in which a tube is necessary on account of their depth and narrowness. By this procedure the wound is put in the best possible conditions for the bactericidal actions of the tissues and the outpoured lymph. It is not wise to impair the resisting and offensive powers of the artificially obtained healthy tissue surfaces by the use of strong or injurious antiseptics. This method, when combined with the surgical essentials of perfect rest, cleanliness, and frequent suitable dressings, has resulted in the healing of projectile wounds, without any appearance of pus in wounds of the skin and of the superficial fascia. In the treatment of some wounds of bone and muscle anatomical problems have prevented these principles of treatment from being thoroughly carried out, so that the results have not been as good. There have been no cases of generalized blood infection, nor of any spreading infection in the neighborhood of the wound.

6. Analgesia in Intranasal Surgery.—W. Wilson describes his technique as follows: One hour before the commencement of the operation a hypodermic injection of ¼ grain of morphine with 1/100 grain of atropine sulphate should be given and the nasal passages packed with gauze soaked in equal parts of 10 per cent. cocaine and suprarenal extract. This should be done with reflected light, so that narrow strips can in most cases be passed behind a marked deviation. The patient should be allowed to remain as quiet as possible for thirty minutes, when he is transferred to the operating table and the gauze strips are removed, a small portion of cotton-wool being inserted far back in each nostril to soak up any overflow from the following infiltration of urea-hydrochloride-quinine solution. In the case of an operation upon the nasal septum three points for injection will suffice on each side; these points are at the angles of a triangle with the base corresponding to the junction of mucosa and skin just behind the anterior nares and the apex over the vomer, its exact position being dependent upon the area infiltrated by the two injections in front. If the inferior turbinals are to be removed two injections will suffice on each side, one just behind the anterior extremity and the other at the junction of the middle and posterior thirds. The syringe employed should be all metal and the needle of the finest aperture procurable with beveled tip without point. Dental needles are most convenient. The solution employed should be 1 per cent. quinine-urea-hydrochloride, and the amount injected should not be stinted. The nose is again packed with gauze wrung out of the cocaine-suprerenal extract solution, and in about twenty-five minutes the operation is commenced. The hemostasis is perfect, and the analgesia is so thorough as to be truly anesthesia, even the tactile sensibility being in most cases destroyed. There is but little emotional distress. The analgesia persists as a rule for about eight to twelve hours. There is no subsequent distress, and the patient is free to go about his business in about twenty-four hours. In consequence of the exudation caused by the quinine-urea solution, there is some after-swelling, but this seems to minimize the possibilities of postoperative oozing. It is quite possible to drain and explore the antrum of Highmore by this method.

5. Note on the Treatment of the Symptoms Arising from Inhalation of Irritant Gases and Vapours. W. L. Symes.

3. Nerve Suture for Bullet Wounds.—R. H. Stoney and H. Meade conclude that the function of a nerve may be interrupted without material injury, in which case the loss of function is only partial and returns early, probably always within a fortnight or three weeks. When a nerve is partially or wholly divided loss of function is marked and permanent, and may even tend to increase. In these cases it is useless to expect spontaneous regeneration owing to the distortion and separation of the cut ends and the great development of dense fibrous tissue which appears to follow in all cases. When a nerve is divided, the sooner an operation for its suture is performed the easier it is and the greater the likelihood of an early cure. In cases, however, in which the wound is septic, it may be advisable to allow time for the wound to heal. Even when nothing has been done for several months, there is still a chance of a successful result if late suturing

is undertaken, so that no case need be looked upon as necessarily hopeless.

5. **Treatment of Irritant Gas Poisoning.** — W. L. Symes finds that of the drugs that have been tried stramonium has, so far, been the most successful. Mixed with a little niter it is readily ignited and smoulders freely. The fumes should, for obvious reasons, be inhaled through the nose rather than through the mouth. Overdosage from absorption of the active principles—atropine, hyoscyamine, hyoscine—through the pulmonary alveoli will be shown so clearly by thirst, by dilatation of the pupil, and by acceleration of the pulse, that dangerous dosage should be readily avoidable. Moreover, it may be anticipated that early and repeated administration will diminish the distressing bronchorrhea of the later stages of gas poisoning. Lobelia, tobacco, and perhaps opium, may fairly be tried, either alone or with stramonium. The objections to the use of opium fumes are obvious and serious. But in the absence of relief from other sources, and given adequate ventilation of the ward, these objections do not suffice to debar a careful trial. Chloroform and amyl nitrite appear to be objectionable, and their use, if adopted, should be carefully watched.

War Aphorisms of a Dermatologist—Cold Feet. — Unna discusses the causes, prevention, and treatment of cold feet. Most soldiers on march who wear leather foot covering have cold feet when the ground is frozen or the weather wet and cold, and when the weather moderates their feet become warm again. Certain others have cold feet all the time and it is not easy to warm them. Not a few never know what it is to have warm feet from autumn to spring. Their feet have to be warmed artificially by wearing felt, or going into heated rooms, and at night they require hot bottles, etc. Such feet may also become warm after vigorous walking. The subject of cold feet has been shockingly ignored. Those who suffer from them have trouble in going to sleep and in concentrating their minds. There is apt to be congestion of the encephalon, and desire for frequent micturition. Cold feet become warm if one removes his socks and places the bare members in boots lined with felt or wool. The laity wrap their bare cold feet in newspapers. Paper is warmer than double socks. The most important requisite for cold feet is moisture; not moisture from without, but that from within, *i.e.* perspiration. This is exhaled from the skin as aqueous vapor, which condenses in the socks and transforms the latter into moist dressings. The constant evaporation of the perspiration necessarily produces cold feet. Dry feet and dry socks could not produce cold. The reason why one person's feet are cold and another's are warm lies in the different tonus of the blood vessels. If this is increased a free circulation of blood is prevented and vice versa. As a substitute for woolen socks, cotton or paper may be "sized" with some substance like resin to render them waterproof. A special sizing may be prepared from collodion, colophony, castor oil, alcohol, and ether. The sock should be inverted and the foot part saturated with the sizing. The soldiers say of them that they are the first warm socks they have ever worn. Their woolen socks may also be sized and are an improvement on unsized ones. In addition, the sole of the foot may be rubbed daily with some fatty ointment, such as tallow mixed with linseed oil. Boots should be worn a size or two too large, so that the empty space may be filled with paper. "Pulse warmers" over the ankle are as serviceable as those worn on the wrists. All these measures are of use in trench warfare.

Treatment of Wounds Due to Shell Fragments.—Israel states that in wounds due to shell splinters the latter should invariably be removed. The wound canal, whether this is penetrating or superficial, must always be freely exposed, and if possible before transportation. Unlike a bullet wound, which is presumably sterile, a shell fragment wound is to be regarded as presumably infected. Shrapnel bullets from this viewpoint are classed with ordinary bullets. It is from shell fragment wounds that we have to fear the development of tetanus and gas gangrene. Some of these wounds may appear benign. The canal is easily exposed and the shreds of dead tissue and clothing easily removed. The wound remains clean and the patient develops no permanent fever. This favorable course, however, is due entirely to the prompt and thorough treatment. In regard to dressings, moist ones are to be preferred, in contrast to the dry dressings indicated in bullet wounds. But the dry dressing must be used during transport. Moist dressings must be changed at least once daily, and, as soon as the wound has cleaned up, an ointment dressing gives much greater comfort than ordinary wet applications. The author does not discuss individual applications.

Ethylhydrocuprein in Pneumonia. — Mendel gives a number of case histories in which this substance under its shortened but proprietary name has been used in lobar pneumonia. It was originally introduced as a synthetic derivative of and substitute for quinine. Under its use recovery occurred in a man of 63 with marked arteriosclerosis and sclerosis of the coronary arteries. Like quinine ethylhydrocuprein has been known to cause amblyopia and tinnitus aurium. The latter can hardly be avoided, but amblyopia, although a transitory phenomenon, apparently does not need to develop. The author keeps the patients on milk and has never seen amblyopia in cases thus dieted. He regards the drug as an absolute specific against the pneumococcus in whatever kind of infection. To claim an efficiency without regard to local factors would be unwise before the remedy has been tested in remote localities, in epidemics, etc. It is not claimed that it is a true germicide, but it may be regarded as an antiseptic or disinfectant which hinders the multiplication of the pneumococcus and weakens its vitality. It must therefore be exhibited in such a manner as to meet fresh exacerbations of germ activity. In this way it acts as an aid to the defensive bodies in the blood, and the broken dose appears to be indicated in place of a therapia magna sterilisans.

Rupture of the Uterus from the Use of Pituitrin.—Züllig refers to the repeated reports of this accident in literature and adds a case in point. The cause nexus comprised abnormally large child, elderly woman (XIII-para) with narrow pelvis and forceps delivery and finally the use of pituitrin. History of artificial premature delivery and perforations. Previous reported cases include the following: Knoop's case, V-para, rupture of uterus after one injection; Herz's case, I-para, age 20, flat rachitic pelvis, rigid os, tetanus uteri and rupture; Espent's case, woman who had had seven normal labors, some disproportion between child's head and mother's pelvis; Stöcker's first case, generally contracted pelvis in a II-para; Stöcker's second case, normal pelvis, previous labors normal, cervix patent, his-

tory of recent abortions and curettings, general condition poor. This last case is seen to differ notably from the rest and gives a new contraindication to the use of pituitrin when the mechanism of labor is normal. In contracted pelves there is very often a history of premature accouchement, perforation of fetal head, etc., representing a vicious circle. Septic abortion also tends to impair the uterine musculature. Hence, next to mechanical impediments to labor the most important factor appears to be intracervical and intrauterine interventions, including dilatation of the cervix, curettage, induction of labor with bougies, etc., perforation of fetal head. The result of such interventions is a weak spot—a cicatrix—in a uterus perhaps already insufficient for the demands upon it. Add to this the violent inception of the pains as a result of the action of pituitrin, and it is evident that the uterus may tear at its weak spot. In the great majority of cases mechanical dystocia will be superadded.

Neurasthenia Cordis. — Graul states that idiopathic cardiac neuroses arise on a substratum of constitutional neurasthenia. The nervous system is functionally inferior, and when local organs are subjected to stimulation a heightened irritability is seen, along with functional insufficiency. The heart is innervated by the vegetative nervous system—vagus-sympathetic—the center for which is in the floor of the fourth ventricle. This center is affected by psychomotor impulse and both organic and functional states of the brain may exert an influence on the heart. Aside from the vagus center the vasomotor center plays a prominent role in the cardiac activity by its action on the blood-pressure, and organic disease of the peripheral vessels likewise directly influence the cardiac activity. The idiopathic cardiac neurosis is equally distinct from organic heart disease and from the toxic and reflex functional anomalies of the otherwise sound heart. Not every neurasthenic has a neurasthenic heart. In fact, the latter may at times be attributed to a congenital imperfection of the vegetative nervous system, seen in connection with habitus asthenicus, lymphatism, etc., which in turn may be due to insufficiency of the endocrine glands. The vegetative nervous system in these patients is extremely unstable, irritably weak, and functionally insufficient as shown by its exhaustibility. The influence of the vagus over the heart, whether through stimulation or paralysis, has been extensively studied and a cumbrous nomenclature has come into use which refers in part to the action on various portions of the heart of the altered vagus innervation. For example, heteroptic stimuli give rise to the extrasystole. Whereas arrhythmia was once regarded as pathognomonic of myocarditis we now know that it may have a purely nervous mechanism. The well known respiratory pulse is so well marked in neurasthenic heart as to be arrhythmic and is almost pathognomonic of the latter. In estimating the relations of cardiac activity to blood pressure it must be remembered that while muscular exercise increases the latter and fatigue diminishes it, the psyche also modifies it through the vasomotor center. Also that in diminished tension the vascular wall is more supple and the pulse has a greater amplitude—just as in increased blood-pressure the amplitude is decreased. In other words, systolic pressure and pulse pressure vary inversely. The systolic pressure does not fall in cardiac weakness. When a subject lies down the pulse slows, but its amplitude is increased. Bodily effort first quickens respiration, increases systolic pressure, and both the amplitude and rate of the pulse. Upon cessation the healthy heart quickly becomes normal, while with insufficiency there is not only no increase of blood pressure, but often a fall. If the peripheral resistance is increased, as by compressing the femorals, the blood pressure rises without increase of frequency, while in an insufficient heart the bloodpressure falls and the pulse is increased. Pressure on the apex of the heart causes a smaller, more rapid pulse in insufficiency. Also in the latter condition standing up after previous recumbency causes considerable disturbance. There is persistent and considerable increase in frequency, arrhythmia, rapid, even dyspneic respiration. The latter may be of the asthmatic type, and then occur by preference at night when the pulmonary circulation pressure is increased as a result of recumbency. In cardiac neurasthenia small heart, "drop" heart and cor mobile are often seen as evidences of constitutional inferiority. There are also tender pressure points over the heart and vicinity—notably under the nipple—and pressure upon these may react as changes in the frequency of the heart beat or its rhythm. Further study of these subjects will show the pressure of a very unstable vasomotor system. The last may be so much in evidence that a separate form of neurasthenia cordis—the vasomotor—has been isolated. Whenever any one symptom common in neurasthenia cordis stands out very clearly above others the latter affection may be excluded. Thus extreme, persistent tachycardia would mean something more than neurasthenia. Neurogenic angina pectoris not a part of the syndrome of neurasthenia cordis. In the latter affection we often find an accidental systolic murmur, heard as a rule over the pulmonary artery, accentuated second pulmonic tone, and duplication of the latter—these indicating a stasis in the lesser circulation. In the present war neurasthenic heart greatly limits the soldier's usefulness if it does not destroy it outright. It is not enough to state that these men are "nervous." They are really ill and require treatment.

Hookworm in a Schoolboy in New York. — Recently while examining the children in a public school in Brooklyn, the attention of the medical inspector, Dr. Max Lederer, was called to a boy 14½ years old, who persistently fell asleep during school hours. Despite his age, the boy was only in the 3B Class and in response to questions made only indefinite replies. Dr. Lederer thereupon consulted the boy's mother and learned that the family had lived in New York only since November, 1914, prior to which time they had been in Jamaica, West Indies. It was further learned that the boy suffered with somnolence at home as well as at school; that he had a voracious and perverted appetite, that he was markedly constipated, and that his mentality was subnormal and sluggish. A physical examination showed a thin, markedly anemic, sleepy-looking, undeveloped boy. Examination of the blood indicated a high degree of anemia and revealed also an eosinophilia of 14 per cent. Examination of the stools was then undertaken and typical ova of the hookworm were found. In association with these were found a few eggs of the tricocephalus dispar. The boy was advised to submit to the approved treatment with thymol and epsom salts. After the second administration of this remedy, the adult hookworm was found in the stools. Since this treatment the boy has entirely lost his sleepiness, he has gained in weight and his mental sluggishness has disappeared.—*Department of Health Weekly Bulletin.*

Insurance Medicine.

Substandard Lives.—In the *Canada Lancet* for May, 1915, Dr. John Ferguson discusses substandard lives. He says that in the first place there are applicants who present a short-lived family history. The relatives that have died have fallen many years short of the expectancy. There is no special tendency to any disease, but there seems to be a lack of endurance. An estimate should be made of how far such family histories fall short of the expectancy of life, on some reliable recent table, such as that of the National Fraternal Congress. Suppose that the deaths of the applicant's relatives point to lowered expectancy to the extent of eight years. The applicant himself is in his thirty-third year and by the National Fraternal Congress table should have an expectancy of 35.4 years. Now, if we reduce this by eight years, we have an expectancy of 27.4 years, and this corresponds to age 43. The applicant, if accepted at all, should be charged the assessment rate corresponding with age 43 and not that for 33, his actual age of entry. His actuarial age of entry is 43. The reduction of eight years in his expectancy has the effect of rating him up ten years.

Turning now to another group of applicants, namely, those who have had syphilis. According to Gowers, Fournier, Florschütz, Blashko, and others the percentage of males infected throughout Europe ranges from 10 to 20. The results of investigations into the mortality experience of insured syphilitics in America and Europe show that it is at least 188 per cent. of the expected. To admit one who has had this disease on the same rate as a healthy person who has not been infected is clearly unfair to the latter. It has been advocated that the age of syphilitics should be rated up to five years, and a candidate of 35 years be called upon to pay as if he were 40. But this is clearly not enough to meet the extra death rate. When one considers all the dangers of the disease, such as gummata, paresis, tabes, arterial degeneration, and so on, Ferguson contends that the average expectation of life of syphilitics is reduced by at least ten years. Now, how would this apply. An applicant seeks admission at the age of 40 who has had this disease. The expectation of life at 40 is 29.9 years. If this be lessened by 10 years the real expectancy becomes 19.9, and this corresponds to age 53. The candidate would have to be charged for this age, if admitted at all.

The next group of applicants that should receive special consideration are those who use alcoholic beverages or are engaged in the manufacture and sale of alcoholic stimulants. Outside of those who use alcoholic stimulants in the most moderate manner, this class yields a much higher mortality than the strictly temperate and abstaining numbers. As a class these applicants must be rated up from 10 to 20 years, according to the amount consumed, and the kind of occupation they follow in connection with the liquor trade. Thus a man of 40 who admits that he consumes alcohol in moderation should be rated up to 50 and pay as of this age. Those engaged as bartenders, employed in breweries and distilleries in the manufacture of liquors, and travelers engaged in the sale of alcoholic products, should be rated up to 20 years. Those who lie between the moderate users and the bartenders or such as imbibe to the extent of periodic drinking bouts, should have at least 15 years added to their ages, so that a man of 30 would be charged the rate of one of 45.

As for overweights, an increase of 5 to 10 pounds over the average for the applicant's height and age will yield an increase of 3 per cent. over the expected standard, then the death rate will go up after mid-life at least 20 per cent. When the weight is 25 to 45 pounds greater than the average, the mortality for 43 years of age and upward will be increased to the extent of 40 per cent. If the person carries from 50 to 80 pounds too much weight the mortality for ages 40 and over will be increased about 60 per cent. Such applicants should be rated up so that the assessments they shall be called upon to pay will meet tihs extra mortality. In such cases they must be regarded as of such an age as will increase their assessments corresponding to their ages and by amounts ranging from 25 to 75 per cent.

With regard to underweights it may be remarked that they do not yield an extra mortality after mid-life. Prior to the age of 40 they yield a higher mortality than the expected. As a class they should be rated up so as to increase their contributions about 15 per cent. By underweight is meant from 20 to 45 pounds below the standard for age and height.

All applicants with a high blood pressure should be subjected to a very careful examination before admission. In the ages from 20 to 35 blood-pressure is not of much importance, but after 35 it becomes increasingly important year by year. A constant pressure of 150 mm. points to some pathological process, even though it may not be discovered. Fistula in ano is a condition that must receive careful consideration. Glycosuria is a form of substandard risk that must be dealt with firmly. The presence of albumin and casts in the urine must also be carefully dealt with. In mid-life when it appears the albumin should be tested several times. With regard to casts, Ferguson does not think so lightly of their presence as some authorities. Few cases call for more careful consideration than a history of pleurisy in the applicant or his family history. Cardiovascular disease calls for refusal in about all cases.

With respect to the acceptance of cases of inflammatory rheumatism, it might be laid down as a rule that if the applicant has had only one attack, not more recently than two years, and that the condition of the heart is quite normal, he may be accepted. On the other hand, if the attack is more recent than two years, or if he has had two or more attacks his application should be refused.

From what has been said it will appear that several plans might be adopted. One of these is placing a lien against the certificate. But societies cannot very conveniently adopt this method. A second plan is that of imposing an extra premium or assessment. The third plan is that of regarding the applicant as a certain number of years older than he really is.

Notification of Disease Occurring Between Application and Acceptance.—That an applicant for life insurance who has answered "No" to an inquiry whether or not he had ever had renal colic is bound to notify the insurer if he has such an attack before the policy is issued, is held in the Tennessee case of Harris v. Security Mut. L. Ins. Co. L.R.A. 1915C, 153.

Book Reviews.

FEDERAL NARCOTIC RECORD BOOK. A daily record of narcotics dispensed or distributed. Price 25 cents. Chicago: The Abbott Alkaloidal Company.

EVERY practising physician requires a narcotic record book of some sort. The present volume is of very handy size, and contains (besides the necessary blank pages) a form for inventory and affidavit. There is also a digest of the Federal Antinarcotic Law, as it affects physicians, pharmacists, veterinarians and dentists. It is a pity that it was thought necessary or advisable to insert advertising matter inside the cover and on the fly-leaf; the presence of such matter detracts from the value of an otherwise desirable volume.

THE CHEMISTRY OF CYANOGEN COMPOUNDS AND THEIR MANUFACTURE AND ESTIMATION. By HERBERT E. WILLIAMS. Price, $3.50. Philadelphia: P. Blakiston's Son & Co., 1915.

THIS book contains an account of the chemistry of the cyanogen compounds, their composition and properties, and a description of the manufacture, application, and estimation of such compounds as are met in commerce. The author has rescued much of the information on the subject that is scattered through the scientific press, and has added the results of his own work. The book is not one that comes within the range of reading of the average medical man.

THE BOOK OF PHARMACOPŒIAS AND UNOFFICIAL FORMULARIES. Containing the Formulas of the British, United States, French, German, and Italian Pharmacopœias, together with Formulas from Unofficial Sources, as the British Pharmaceutical Codex, the National Formulary of the United States, the Pharmacopœias of the Principal London Hospitals, etc., the whole comprising about 5,000 Formulas. By E. W. LUCAS, F.I.C., F.C.S., Pharmaceutical Chemist; late Examiner to the Pharmaceutical Society; Member of the British Pharmacopœia Reference Committee; Author of "Practical Pharmacy," "The Book of Prescriptions," "The Book of Receipts," etc. And H. B. STEVENS, F.I.C., F.C.S., Pharmaceutical Chemist; Lecturer on Pharmacy and Materia Medica in the Southwestern Polytechnic Institute. Price $3.00. Philadelphia: P. Blakiston's Son & Co., 1915.

THIS volume contains in a handy form a conspectus of the chief formularies and pharmacopœias. The work will be of special value to pharmacists; but physicians whose reading extends to foreign literature will find the work of use in enabling them to compare the preparations of other countries with those of their own. Thus, to take but one illustration, reference to page 320 will show the difference in the composition of Dover's powder in the Pharmacopœias of Great Britain, the United States, Germany and Italy, and in the French Codex. At the end of the book will be found an alphabetical table of the French, German and Italian vegetable Materia Medica, together with the common English equivalents.

SELECTED ADDRESSES on Subjects Relating to Education, Biography, Travel, etc. By JAMES TYSON, M.D., LL.D., Professor of Medicine, Emeritus, University of Pennsylvania. Price, $1.75. Philadelphia: P. Blakiston's Son & Co., 1914.

THESE addresses were delivered on various occasions between the years 1884 and 1912. Like most volumes of this class, the value of the contents is that of the occasions on which the addresses were made. The present collection is interesting and, while there are no oratorical flights, the "efforts" are all characterized by sturdy common sense and healthy and honest ideals. Two of the papers seem to us to be of more than ordinary value, namely, those on Hospital Organization and The Trained Nurse. Pupils and admirers of Dr. Tyson—and they are many—will be glad to possess this volume.

DIABETES MELLITUS. Designed for the Use of Practitioners of Medicine. By NELLIS B. FOSTER, M.D., Assistant Professor of Medicine, Cornell University; Associate Physician to the New York Hospital. Price, $3.00 net. Philadelphia and London: J. B. Lippincott Company, 1915.

THE amount of literature that has grown up about the subject of diabetes mellitus is nothing short of appalling to the man who is anxious to learn the essential facts about the disease. A great part of this literature consists in acrimonious criticism or undiscriminating support of some theory or other, so that only a trained and enthusiastic worker is able to separate the true from the false. Foster is apparently such a trained enthusiast, who has attempted to write "a critical presentation of the evidence as it exists at present." He attacks his problem in a logical, orderly manner and because he understands the subject so thoroughly is able to present it in a form that is easily understandable. His critical ability is nowhere more prominently shown than in the chapter on Acidosis, where he demonstrates how well he has learned from Pflüger how to differentiate between "what may be and what is proved to be" (note p. 47). He shows clearly that according to our present evidence, ketonuria is a result of carbohydrate deprivation whether due to a carbohydrate-free diet or to the inability of the body to use carbohydrates. "There is no essential difference between the ketonuria of sugar-starvation and severe diabetes." The chapter on History is but three pages long, yet covers the ground thoroughly. It is, however, in his discussion of the treatment of this disease that he will be of the greatest help to his fellow-clinicians. Patiently and in great detail he considers one point after another, giving sample diets and recipes, and leaving nothing to the imagination. Of equally great importance is a brief chapter on the Identification of Sugars, with which the book closes. There is no work which handles the subject as well or which will prove of such benefit to the clinician in the treatment of his diabetic patients.

TRANSACTIONS OF THE AMERICAN SURGICAL ASSOCIATION. Vol. XXXII. Edited by ARCHIBALD MACLAREN, M.D., Recorder of the Association. Philadelphia: William J. Dornan, 1914.

IN this volume we have the usual lists of officers and members, a section devoted to short biographical sketches of fellows deceased during the previous year, and the papers read at the annual meeting of the Association in New York, April 9, 10, and 11, 1914. The fellows deceased since the last volume of the Transactions was issued include Maurice H. Richardson, Nathan Jacobson, Arthur T. Cabot, Roswell Park, and Joseph D. Bryant. This volume, as usual, contains papers of a high degree of excellence, and it is also enriched by the contributions of a number of visiting surgeons from abroad—Nicolaysen, of Christiania; Henri Hartmann, of Paris; E. Panzi, of Vienna; H. Kümmell, Hamburg-Eppendorf; Richard Sparmann, Vienna; Robert Proust, of Paris; Antoine DePage, of Brussels, and Professor Rehn, of Frankfort. Since all the papers have been published elsewhere, comment on them is unnecessary except that their collection in one volume makes this copy of the Transactions a highly valued addition to one's library.

BURDETT'S HOSPITALS AND CHARITIES, 1915. Being the Year Book of Philanthropy and the Hospital Annual. By Sir HENRY BURDETT, K.C.B., K.C.V.O., author of "Hospitals and Asylums of the World," etc. Twenty-sixth year. London: The Scientific Press, Limited.

BURDETT'S Hospital and Charities is *sui generis* and an almost indispensable work of reference to the physician and surgeon, and especially to those who are interested in the progress and well-being of hospitals and charities. It is true that in this country, as in Canada, hospitals are not conducted on the system of charity prevalent in Great Britain, but at the same time the book is such a mine of information that it is nearly as useful to the American practitioner as to his British confrère.

The present volume is a revised form of the twenty-fifth volume and contains many important alterations and some useful additions. It is pointed out that national insurance in Great Britain has materially affected the admissions to and consequently the accommodation at and position of many infectious hospitals throughout the country. It is also worthy of notice that owing to the chaotic condition of hospital accounts in the United States and the difficulties experienced in acquiring accurate information regarding hospitals in the United States, Canada, and Australia, the information given concerning such institutions in these countries is neither so full nor so reliable as one could have wished. However, considered from all standpoints the book is unique and a credit to the painstaking zeal of Sir Henry Burdett and his collaborators.

Society Reports.

AMERICAN ASSOCIATION OF IMMUNOLOGISTS.

Second Meeting, Held in Washington, May 10, 1915.

THE PRESIDENT, DR. GERALD B. WEBB, COLORADO SPRINGS, COLO., IN THE CHAIR.

The Value of Vaccines in Certain Diseases of the Ear, Nose, and Throat.—Dr. GEORGE M. COATES of Philadelphia presented this communication, limiting his discourse to the more common uses of this form of therapy and to the cases in which one might expect success, mentioning briefly some of those in which success could not be expected. He stated that his conclusions were drawn largely from his own work and that of his friends and colleagues in Philadelphia, though he had had due regards to the reports in the literature. Successful vaccine therapy of the ear, nose, and throat was not as easy as it might seem. It did not consist in buying a bottle of mixed vaccines and giving hypodermics according to the label on the bottle. Some good results might be thus obtained, but there would be many sad failures. Close study must be made of the individual case and the reactions observed to determine all but the first dose. A good autogenous vaccine was usually superior to any other form, but it was not to be contended that a good commercial product was not better than a poor autogenous one, and a poor commercial one was no worse than a poor autogenous one. A stock vaccine could be kept ready for use at a moment's notice and was of value in cases in which an autogenous preparation could not be used, as for prophylaxis. For immunization against acute rhinitis where a variety of organisms were usually found, a commercial mixture or some or all of these organisms was selected, and three or four injections given at three or four days intervals, the dosage depending somewhat on the individual, the age, size, etc. Whatever the initial dose might have been it was usually doubled for each succeeding dose, unless there was too marked a local or general reaction. This should insure the ordinary person against an attack for some months, but in very susceptible individuals the entire course might have to be repeated. The failures as a rule were in those particularly susceptible to colds, and having one after another in close succession. Most of these, however, had the duration of the attacks lessened and the interval between them lengthened. The treatment of acute rhinitis was exactly the same as for prophylaxis except that it was pushed a little more vigorously and continued until the trouble had been conquered. Following the first dose, and this was true of all the conditions considered, there would probably be some exacerbation of the patient's condition with increased discharge which soon cleared up in favorable cases. This reaction was regarded as a favorable omen. Chronic rhinitis was to a certain extent also influenced by bacterins, but here the treatment must be extended and the patient closely watched lest he become overtreated. Suppurations of the accessory nasal sinuses were not much relieved by vaccine therapy until adequate drainage had been established. In chronic sinusitis it was usually necessary to enlarge the normal ostium or make a large artificial opening before much could be expected from the use of vaccines. In acute cases the results were good for the most part and a stock suspension might be used in order to get quick results, at least until an autogenous one could be prepared. It would not do to give vaccines for any acute headache that seemed to be of nasal origin; the diagnosis must be established. There were certain cases of chronic sinusitis in which vaccines prepared the way for operation. Recurrent furuncles about the alae nasi and close to the alar cartilages, usually caused by one of the staphylococcus group, yielded in a most satisfactory manner to vaccine treatment. Treatment was usually started in these cases by a stock suspension of staphylococcus aureus and albus, and if this was not successful, an autogenous vaccine was made later. This also applied to furunculosis of the external auditory canal. In atrophic rhinitis and hay fever the vaccine treatment had not been particularly gratifying. The treatment of diseases of the ear by bacterins had yielded surprisingly good results although some were still skeptical regarding it. Considering the close relationship between nasal and aural infections, it was only reasonable to suppose that if ear patients could be immunized against nose and throat infections one was in a much better position to treat the ear disease. In chronic catarrhal deafness astonishing results could not be looked for. In cases of acute suppurative otitis media of scarlatinal origin the writer was quite sure that by the use of autogenous vaccines the duration of the disease was materially shortened and many cases were kept from drifting into the chronic class. During the past winter the author and his assistant, Dr. M. S. Ersner, had made autogenous vaccines for about 42 chronic cases of suppurative otitis media at the Pennsylvania and Polyclinic Hospitals and so far they had obtained dry ears in about 40 per cent. These cases had all been carefully selected as having had and resisted all the usual forms of treatment and they took no account of improvements. An ear must have ceased entirely to discharge in order to be considered cured. They had also been successful in a number of instances in which the *Bacillus pyocyaneus* was the infecting agent. Improvement in general health and resistance to other forms of infection were observed in those that responded favorably to the vaccine treatment. There were many factors that mitigated against the potency of a vaccine, and in nose and throat work a frequent cause of error was in taking the culture. It took a trained aurist to take an uncontaminated culture from the middle ear or naso-frontal duct. The essayist said his method was as follows: The external canal, membranæ tympani, and middle ear were cleaned thoroughly by means of suction apparatus and cotton swabs. Alcohol or alcohol and bichloride were then rubbed back as far as the drum to sterilize the external canal. By inflation through the Eustachian tube or by suction to the external meatus pus was forced from the recesses of the attic by a tube mouth. The culture was then taken with a platinum pool, or a very small amount of cotton wound on a steel applicator thoroughly sterilized. If no results were obtained after a few injections of a vaccine it was considered impotent and a fresh one prepared. The organisms found in by far the greater number of their chronic middle ear suppurations were the *Staphylococcus aurcus* or *albus, Bacillus pyocyancus* and diphtheroid bacilli. The pneumococcus was found much less frequently; *Staphylococcus citrus* was found twice and the organism of Vincent's angina twice. Since employing the technique just outlined pure cultures were frequently obtained, whereas by the older methods it was not unusual to find two or three organisms in the culture. Streptococci were often found in the acute cases but rarely in the chronic ones.

Dr. FREDERIC E. SONDERN of New York said he was very much interested in the paper of Dr. Coates because it had been his fortune to see specimens of the type he described and he would like to agree with him in reference to what was said in regard to the use of the autogenous vaccines. He had seen repeatedly good results following their use. He was present when Nagel read his paper before the Triological Society in Washington and his results were astonishing in vaccine therapy. His description of the negative and positive phase interpreted clinically was beautiful and showed a very close observation. Dr. Sondern knew of many otologists who tried to follow out the methods of Nagel but with little or poor results. In ear cases the successful outcome following the use of the vaccines depended upon the condition in the ear. If there was dead bone present they would not get the results desired. The same thing applied in using vaccines in cases of sinus disease and inflammations of the mucous membrane in the nose. Dr. Sondern, however, had seen very gratifying results following the use of the vaccines; but if the nose was so occluded that the patient could not draw air through, especially if there was a sinus obstruction with pus present, he believed the use of the vaccines was useless.

Dr. MARTIN J. SYNNOTT of Montclair, N. J., referring to the use of the vaccines in hay fever, said he understood that there was no preparation of the stock vaccine in the market. This might be true in the United States but there was a stock vaccine from Wright's laboratory in London which he had been using for two years; it was called pollicin vaccine and was the result of the work of one of Wright's assistants. He had produced a diagnostic outfit which was to determine the susceptibility of the patient; it was used in the eye to test the conjunctival reaction. The dose was then determined upon. This method was found to be very troublesome because the patient objected to having the

vaccine instilled in the eye; they dreaded any possible injury to that organ. It had been Dr. Synnott's practice (he had had twenty or thirty cases which gave encouraging results) to give small doses of the vaccine, usually 0.1 c.c. This was given twice a week and then increased 0.1 c.c. unless there resulted results either focal, local, or constitutional.

Dr. A. Parker Hitchens of Glenolden, Pa., said that he had had but a limited experience in the treatment of hay fever but he had had a chance to use injections of the pollen extract in both the treatment and prevention of this malady and a few things he had been able to observe he thought might be of interest to the members of the Society. One of the most interesting things to be noted was the difference in the intervals necessary between the doses if they wished the patient to be entirely free from symptoms. He did not know what the pollen extract did, whether it used up the specific ferment or accumulated products which prevented the ferment from acting; just what it did he did not know; this remained for the future to explain. A dose of the pollen extract was followed he believed in nearly every case by a relief of the symptoms; that was, if they gave the specific pollen or protein. The majority of the cases of so-called hay fever were undoubtedly due to certain pollens. In the fall they met with the rag-weed; in the spring orchard grass and red top were chiefly responsible. He had one patient with hay fever which probably resulted from proximity to the magnolia trees. This individual had hay fever through both seasons. The first year Dr. Hitchens tried him on injections every seven days, but he soon noticed that he began to have symptoms about the end of the fifth day. He kept on giving these injections every seven days regularly but he continued to have violent attacks two days prior to the next injection. He then shortened the time to five days and the patient had no more symptoms. The giving of these injections at longer or shorter intervals depended upon each individual. Dr. Hitchens believed that every rational treatment for the prevention of hay fever should be preceded first by the diagnostic test. He believed that the experience of many men with the ophthalmic reaction as used in tuberculosis would cause them to hesitate using this method in the eye and he did not really think it was necessary to use the eye as a test at all. The intradermal test gave as good indications as the ophthalmic reaction. His experience with nasal and respiratory conditions was somewhat limited but interesting. He had under his care one young woman who had been afflicted with asthma the previous winter. Following the use of small doses of autogenous vaccine once a week, she was relieved of her asthma. He asked those present who had had experience in dealing with cases of hay fever if they could corroborate the statement of Dunbar who stated in the Journal of Hygiene that he had injected many normal persons with pollen extract and none had become sensitized. Did sensitization depend upon these injections or anything of that kind? Dr. Hitchens thought that one of the most important points brought out in Dr. Coates' paper was that the bacterial vaccine must be used with brains; that should be an axiom. About 90 per cent. of physicians did not use their brains when using the vaccines; if they got no results, they would say they were of no value. No good could come from the use of the vaccine unless the antibodies formed came in contact with the bacterial factor. Every practicing physician should take this into account. They were amused at the horrible things which might happen if one who was an expert in the use of the pollen extract did not use it. Dr. Hitchens said he had given about 1500 injections and never had he the slightest cause for alarm.

The results often left one with the suspicion that there was something else in the vaccine besides the pollen. Vaccines were valuable before operations for infections of the upper respiratory tract; a shorter or longer course of vaccines should be given before these operations were performed. They had seen no harm result from anaphylaxis. In the tissues were antibodies and proteins; any proper antigen placed in the tissues exerted a favorable influence. If the ferment did not exert a specific function, helping to get a reduction of the infecting bacteria, not coming in contact with the infecting bacteria, or something else, there was some fault somewhere.

Dr. E. C. L. Miller of Richmond, Va., said that certain observations made it appear as though hay fever caused an anaphylactic reaction. After the injection of protein the patient appeared to be desensitized and more or less stimulated; after desensitization possibly other symptoms might occur. If they continually injected patients with the same antigen he asked if the patient would not become worse than he was before.

Dr. Gerald B. Webb of Colorado Springs, Colo., said it was a reproach to the medical profession that it never dealt with the so-called "common colds." He thought that all of them had seen benefit result from the plan outlined by Dr. Coates. Perhaps and possibly the colds were not all caused by the organisms they thought they were. It had lately been stated that these colds were due to filter passers. In London they found many cases of pseudo-diphtheria which were called colds. It was well known that influenza came in waves; in Colorado they had not met with the influenza bacillus for some five years. During this time, however, they met with cases that looked like grippe but there were present no influenza bacilli. It seemed that conditions simulating grippe could be produced by filter passers. They were able to ameliorate the catarrhal conditions but yet they did not seem able to hit the nail on the head. They could get some benefit from the inoculation of the catarrhal organism, diminishing the discharge, but they did not cure the patient. By passing the discharge from the infection through filters and then spraying the filtrate in the noses of students they could produce a severe influenzal cold. The last word had not yet been said regarding the cause of catarrhal colds. Regarding the use of apocynum, injections of this drug might entirely cure ear infections. Regarding hay fever, patients were susceptible to more than one pollen. Cotton wood caused the trouble in some cases. In the treatment they employed they sometimes combined the catarrhal organism with the pollen vaccine. In one-half of the cases treated, successful results followed. With regard to the dangers following this method, one laboratory worker was very susceptible to cotton wood and he had a tremendous reaction. The breathing caused them considerable alarm. He thought that possibly there was some foreign body present.

Dr. George Morrison Coates of Philadelphia closed the discussion. He said that colds treated lasted about ten days; if untreated, they lasted probably eleven days. The pyocyaneus bacillus infection was not always considered a secondary infection. A few days ago he did an operation for acute mastoiditis and obtained a pure culture from the mastoid cells. In all his operations for mastoiditis, cultures were always made and vaccines were regularly administered after operation, and his patients seemed to get well in a shorter time. McKernon of New York, in cases of mastoiditis following scarlet fever or measles, used the autogenous vaccines and this reduced the time of healing to a considerable extent. In ear cases, the results of Nagel's work brought about much skepticism, but his work could be vouched for. In certain ear cases of chronic type, even when necrosis was present, they could raise an artificial immunity and terminate the necrosis. It might take longer but in the presence of a slight degree of necrosis the use of the vaccines influenced the course of the disease very materially.

Election of Officers. — *President*, Dr. J. W. Jobling, College of Physicians and Surgeons, Columbia University, New York City; *Vice-President*, Dr. George P. Sanborn, Boston, Mass.; *Councilman*, Dr. John A. Kolmer of Philadelphia, Pa.; *Treasurer*, Dr. Willard J. Stone of Toledo, Ohio; *Secretary*, Dr. Martin J. Synnott of Montclair, N. J.

President's Address: Pasteur.—Dr. Gerald B. Webb of Colorado Springs, Col., made this address in which he stated that in rereading Pasteur's life it had occurred to him that they as immunologists could not hear too often or too much of this, their greatest master. Pasteur's advice to the students of the University of Edinburgh was "Worship great men." He agreed with the anonymous writer in the *Spectator* that "he was the most perfect man who had ever entered the Kingdom of Science." He reviewed the early history of Pasteur, showing that he was fortunate in his parents, having a father reserved and of a slow and careful mind and a mother, active, full of enthusiasm, and of imagination. He was equally fortunate in choosing a wife who was willing that the laboratory should be put before everything else. The speaker dwelt on Pasteur's work on fermentation, and his discoveries with reference to the disease of yeast and of the silkworm and of what these meant to the wine, beer, and silk industries of France. He reviewed the other discoveries of this great scientist which were familiar to them all. In speaking of Pasteur's attitude during the Franco-Prussian War, he said that he was unable to concentrate on his work and

wrote, "This war has sent my brains to grass." Later he wrote: "Might and right struggle for the world; right which constitutes and preserves society; might which overcomes nations and bleeds them to death." His writing on the psychology of war and his description of the horrors he witnessed formed a counterpart of similar crimes reported recently, and in closing a discourse on this subject he wrote: "But we may assert that French Science will have tried, by obeying the law of Humanity, to extend the frontiers of life." In 1874 Tyndall, after thoroughly investigating Pasteur's experiments, wrote: "For the first time in the history of Science we have the right to cherish the sure and certain hope that, as regards epidemic diseases, medicine will soon be delivered from quackery and placed on a real scientific basis. When that day arrives Humanity, in my opinion, will know how to recognize that it is to you that will be due the largest share of her gratitude." After relating still further the discoveries of Pasteur Dr. Webb stated that it was not generally known that the first experiments in "carriers" dated from him. Pasteur was much more forceful than his biographers had indicated. He rarely visited a theater or went out socially, feeling like the philosopher who said, "I am never bored but when I am being entertained." Pasteur read only what was good, and especially selected biographies. His advice to students should be emphasized. "All experimental research must be guided by some preconceived ideas. Exhaust every possible combination, until the mind can conceive no other possible. It is indeed a hard task when you believe that you have found an important scientific fact, to constrain yourself for days, weeks, years sometimes, to fight with yourself, to try and win your own experiments, and only to proclaim your discovery after having exhausted all contrary hypotheses." In closing Dr. Webb advised his hearers to read the Life of Pasteur by Valley Radot, a book which he described as reading like a fairy story and one which should be memorized by all.

A Clinical Study of the Comparative Results of the Wassermann Reaction.—Drs. A. A. UHLE and WILLIAM A. MACKINNEY presented this paper, in which they stated that under no circumstances should a diagnosis of syphilis be based on the result of the Wassermann reaction alone. The serologist's report should be positive or negative, and if it was at variance with the clinical expectancy, other specimens of blood should be submitted to one or more serologists for confirmation before such a result should be seriously considered. A negative Wassermann did not exclude syphilis, since such a reaction might be obtained in the early stages of chancre, or might be the result of active treatment, or might exist in latent syphilis in which the foci of disease were not active to the extent that antibodies might be detected by the test. In latent syphilis a negative reaction at times became positive after active treatment. In certain cases of nervous syphilis the serum Wassermann reaction might be negative and the spinal fluid Wassermann reaction might be positive. After an intraspinal injection of salvarsanized serum, a formerly negative spinal fluid Wassermann test might become positive. Many competent observers had reported positive luetin tests with a negative serum Wassermann test. Certain factors irrespective of the test itself were considered responsible for discrepancies; these included the age of the serum, infected serum, non-sterile test tubes, the character of the glass of the test tube, changes in the blood as the result of faulty metabolism, influence of alcohol, etc. It could be readily understood why discrepancies should exist in reports from different laboratories, conflicting reports from the same serologist upon specimens from the same individual withdrawn at the same time under identical conditions were not easy to understand. After discussing the discrepancies in the Wassermann reports with several serologists, it was decided that a series of blood specimens from approximately 300 patients be submitted for examination in order to ascertain to what extent the above mentioned factors influenced the Wassermann test. The first part of the work was done by four serologists and later three more cooperated. These men were all representative serologists connected with teaching institutions. The blood was collected from normal individuals, from patients in private and hospital practice who suffered with diseases other than syphilis, and from syphilitics in practically every stage of the disease. With a few exceptions all the syphilitic patients had been under their care for some time and several Wassermann tests had been reported on them before this study was undertaken. The blood was collected under the usual precautions and the specimens were so tabulated that those making the tests knew nothing of the source of the specimens. These specimens were taken when the stomach was full and when empty. In one series two tests were made on each specimen, one of which was a non-infected serum, while the other was infected with virulent pathogenic organisms. In another series the serum Wassermann and the spinal fluid Wassermann were studied comparatively. In latent syphilis a classification was made of those who at the time of the taking of the blood showed no demonstrable lesion of the disease, irrespective of its duration. The periods of latency were classified according to the duration of the disease. The authors exhibited fifteen tables showing the results of these tests by the different laboratories and a number of summaries explaining them, from which they concluded that it seemed to them that the extreme variations in the results of the Wassermann test on blood serum, taken from the same individual under identical conditions as they were reported by several serologists, were not due to any of the factors which were frequently considered responsible for such discrepancies. The same variations occurring when the blood was collected in a sterile or a non-sterile tube; when infected by certain pathogenic bacteria, or irrespective of the time elapsing between the collection of the blood and the time of the examination. In non-syphilitic cases a positive Wassermann report might be expected in from 2 to 18 per cent. of the cases; in active primary, secondary, and tertiary manifestations of syphilis, with the exception of the first few days of a chancre, a positive Wassermann was present in from 50 to 100 per cent. of the cases. In syphilis under active treatment, or when the condition was latent the result of the Wassermann reaction was of the utmost importance to the clinician and it was in these conditions that the most extreme variations were reported. In the study of these cases it became clear that the discrepancies in the Wassermann reports, made by the different serologists, were due to errors in technique, or lack of proper standardization of the reagents.

Pseudopositive Wassermann Reaction in a Case of Uremia and Intestinal Toxemia.—Dr. JUDSON DALAND of Philadelphia reported this case which occurred in a man 55 years of age, a plumber by occupation, who was admitted to the hospital on February 10, 1911. There was ascites, edema of the lower extremities, penis and scrotum, moderate dyspnea which became extreme upon assuming recumbency and after slight exertion, and slight cyanosis of the fingers and lips. There was nothing of importance in the family history or habits of the patient. His present illness began January 16, 1911, when he felt as though a nail had been driven into his left knee and a few minutes later swelling was observed in the feet and knees rapidly involving the legs which was rapidly followed by ascites. The physical examination showed extreme pallor, poor musculature, cyanosis, a few enlarged glands in the neck, axilla, and groin. The pupils contracted equally and responded normally to stimuli. The teeth were absent. The apex beat of the heart was one-half inch to the left of the nipple and the impulse was heaving. The area of heart dulness was increased more especially to the left. The pulse was regular in force and rhythm, compressed with difficulty, and the radial arteries were sclerosed. The first sound was rough and accompanied by a blowing systolic murmur, transmitted to the left axilla. A similar murmur was heard over the aortic cartilage and was transmitted into the neck. The aortic sound was accentuated. The liver was slightly enlarged. The diagnosis was chronic interstitial nephritis and uremia in association with intestinal toxemia. The records of the blood pressure, blood examinations, urinary examinations were presented. The four Wassermann tests taken at intervals during the two weeks following his admission to the hospital showed one three plus Wassermann, two positive reactions, and one plus minus reaction, this being the last of the four. The urine showed a moderate amount of albumin with hyaline and granular casts and a large amount of indican.

Dr. JOHN A. KOLMER of Philadelphia, Penna., said he felt that the other side of the question as to the specificity of the Wassermann reaction needed some defense. He had been interested in the question of the antigens, especially with the cholestrated extract, for several years. He had followed many patients through the clinical course of the disease and had made comparisons with the aid of several clinicians as to the Wassermann findings. He was of the opinion that this reaction was

due primarily to a difference in the antigen. With a proper understanding of the mechanism of the Wassermann reaction the proper use of the antigen would modify their results more than anything else, more than any other factor. He did not believe the alcoholic extract of a syphilitic liver a specific antigen. The question of the specificity of the Wassermann reaction was a fallacy. This was especially true as regards the aqueous extract of rabbits' livers. Two years ago he worked with a pure culture which was furnished him by Dr. Noguchi of New York. He believed the specificity of the Wassermann reaction did not depend upon the antigen but upon the nature of the antibody. The antibody played a big part, or constituent, of the Wassermann. It was their purpose for three or four years to use three different extracts; one to be reinforced with cholesterine; another, the alcoholic extract of syphilitic livers as used in the United States and Germany, and another, the use of an acetone which was insoluble, and extract prepared after the method of Dr. Noguchi. They found the highest percentage of reactions were obtained when they followed the method of Dr. Uhle. The use of the alcoholic extract of syphilitic livers yielded the poorest results. He believed that the reports given by the members differed in the Wassermann reaction, coming from different laboratories, not because of any difference in the technique but because of differences in the antigens. A review of the early literature regarding the specificity of the Wassermann reaction was entirely misleading. The reports regarding scarlet fever were misleading. In his experience with 250 cases only seven gave a reaction, and two had either a macular or papular rash of syphilis. From the standpoint of the laboratory man they respected the specificity of the Wassermann. He had found it on three occasions in the tubercular variety of leprosy. He had found it also in yaws. Syphilis should be diagnosed in the laboratory. The statement that the patient did not have syphilis did not exclude this disease; many of these patients had their symptoms cleared up when under treatment and made it presumably evident that the patient suffered from a true case of syphilis.

Dr. KENYOUN of Washington, D. C., agreed with what was said regarding the specificity of the Wassermann reaction and the importance of reinforcing it with antigen. He believed that many discrepancies found in the laboratories were due to the fact that different antigens were used. There was one important thing that should be called to mind—in the series of cases Dr. Uhle mentioned, ascertaining at what time the reaction was made in the given blood, whether before or after taking in food. It was well understood that those who partook of alcohol in considerable quantities had the Wassermann much modified. He had ascertained that in many cases where the reaction would be negative during the first twenty-four hours, if the reagent was kept for one week or ten days at a proper given temperature, many of the sera would become positive.

Captain VEDDER, U. S. A., said he was in accord with what Dr. Kolmer had stated and especially what he said regarding a proper diagnosis which should not be made on a positive Wassermann reaction alone. They all knew that lesions of syphilis could occur without any history or clinical signs being manifested. He told of a prominent physician who came to the laboratory and gave a strong positive reaction. This man was a prominent dermatologist from New York. He said: "I may have a positive Wassermann but I have no syphilis." There was found a serious heart condition which was probably due to syphilis. He was positive that at no time had he acquired this disease. There were a certain number of cases which could only be diagnosed by the Wassermann test. With regard to the normal cases in which the reaction varied from 0 to 10 per cent he said he had just completed a series of surveys. Among 1500 soldiers he could report a positive reaction in about 3 per cent. Does obtaining a positive Wassermann reaction mean syphilis, or did it not? There were no doubt many cases of syphilis that did not come to the physician had syphilis which could only be detected by the Wassermann. Dr. Park of the New York Health Department had given 500 consecutive sera and the discrepancies were not so great as might have been supposed.

Dr. RICHARD DEXTER of Cleveland, Ohio, agreed with Dr. Kolmer that the antigens were a variable factor. The result of his observation showed that the cholesterine antigen gave a finer test than did others. He reported the case of an insane young man who recently came under his notice and whose spinal fluid was submitted for examination. The patient had been shot through the orbit and there was a fracture of its upper part. The examination of the spinal fluid was negative first. But during the following week he developed a syphilitic meningitis and the examination of the spinal fluid since had been positive. It was first thought that he had a staphylococcus infection.

Dr. JUDSON DALAND of Philadelphia, Pa., referred to the discovery of living *Spirocheta pallida* after the administration of salvarsan. He believed that chancres should be primarily excised and then neosalvarsan given. Ehrlich found no spirochete and no chancre at the expiration of twenty-four hours after the injection. Those present could not help but appreciate the work that had been done by Dr. Uhle. These results were obtained from various specimens and from various laboratories. This was an important question yet to be solved. Dr. Daland said the experiences just reported were very important and the discussion, too, was very important as pointing out the need of a careful interpretation of what was found. If one obtained a positive Wassermann it did not necessarily mean that the individual had syphilis; if one got a negative result it did not necessarily mean that the patient did not have syphilis.

Dr. CLAUDE P. BROWN of Glenolden, Pa., said that in a series of cases in which salvarsan was administered the spirochete were still present.

Dr. UHLE closed the discussion. He said he knew nothing about the technique and what he had presented was from the clinical standpoint only. In speaking of the Wassermann reaction serologists say they wished to obviate the causes which gave rise to a positive reaction. It might be that cholesterine antigen, or the alcohol antigen, might be better. The workers as yet had no specific antigen which they could rely upon. With regard to the diagnosis clinically of gumma of the liver, here there was something wrong; here they could only go by the history of the case and the family history. In such cases the use of the antigen was of great value. He asked what it meant, sending ten samples from the same individual, withdrawn at the same time under identical conditions, to the laboratories and getting the returns that six were positive and four negative. The best they could do was to watch the work of the different workers in the laboratories and determine who did the best work and then to rely upon his interpretations. He recalled one worker who was sent 103 specimens and he did not fail once in making a proper interpretation. Later ninety-three plates were sent and the laboratory diagnosis was correct. There were other things besides antigens which could account for certain discrepancies. One of his friends was a serologist, but his reports were not as good as those of other serologists. The work was often done by dealers who were trained to make the Wassermann test. He thought it was largely a question of technique; let the dealer do the daily work but do not let them interpret the findings; that would be a mistake. What had been presented by them in the paper was but a preliminary study. They hoped in the near future to be able to present some uniform technique, a uniform antigen, and hoped then that the laboratory would greatly aid in the clinical diagnosis.

The Vaccine Treatment of Ringworm of the Scalp.—Dr. ALBERT STRICKLER of Philadelphia, presented this paper. He stated that the vaccine treatment of ringworm of the scalp rested upon the fact that there was developed in the blood of children suffering from this affection, a specific antibody which produced a positive complement fixation test and gave a positive skin reaction. Dr. Kolmer and the author had found 78 per cent. positive fixation tests in children suffering from tinea tonsurans. When they injected 0.056 c.c. of a suspension of dead ringworm fungus in salt solution, which had been briefly centrifuged at a low speed, so that it was about the same density as luetin, and injected it into the superficial skin of the arm of a child suffering from tinea tonsurans, they obtained a reaction in the vast majority of the patients with ringworm and negative results in their controls. After describing in detail their method of getting the vaccine for tinea tonsurans, the essayist stated that their success had depended upon the incorporation of the entire fungus growth in the vaccine: the failure of the psychophytins of Plato was probably due to the fact that the culture suspension was subjected to filtration. Too much emphasis could not be placed on this point and

on the necessity of rubbing up the ringworm growth From the growth in an ordinary Ehrlenmeyer flask about 500 c.c. of vaccine was made up. To this 8 to 10 c.c. of chloroform was added to kill the growth, and the vaccine was heated for one hour at 600° C. The use of the chloroform was latterly discontinued. Controls for living fungi were made on French "proof agar," and for pyogenic organisms on plain agar. The vaccine was preserved by the addition of sufficient phenol to bring it up to 0.25 per cent. It was then tubed in sterile vials and was ready for use. The vaccine might be employed in doses varying from 5/10 c.c. up to 4 c.c. It had been found of no value to employ a dose as large as the latter. The usual dose varied from 0.5 c.c. to 2 c.c. The injections were given at intervals of three days, but later it was deemed advisable to give them every five or six days. The injections were given preferably in the region between the scapulæ. The number of injections varied from seven in some patients to twenty in others. In no instance was there any constitutional reaction. After the patient had received six or seven injections, a local reaction in the form of an infiltrated area developed in about thirty-six hours after the injection, at the point of injection. In treating a case of ringworm of the scalp, hair infected with the fungus was planted on "French Proof Agar" according to the technique described both for the purpose of determining the type of infection and for the purpose of treatment. They then injected the patient with their stock vaccine, once every five days, giving five injections, the first 0.5 c.c. and giving one c.c. for the second and third injections. They then advised local treatment (cade and olive oil in equal parts) for a period of two weeks, meanwhile giving 1.5 c.c. of the vaccine every six days. This local treatment was then followed by the use of an ointment (precipitated sulphur, gr. xx, vaseline ʒi), which might be applied once a day for a period of ten days or two weeks. The vaccine treatment should extend over a period of from two to three months. Up to date they had treated at the Philadelphia General Hospital, twenty patients with ringworm of the scalp of varying degrees of severity. Of these fourteen had been cured, two markedly improved, two improved but left before treatment could be properly carried out, three died from measles and one from pneumonia. All of these were treated with vaccines, only a weak ointment being used to stimulate hair growth in three cases. If after giving seven or eight injections no improvement was noted the stock vaccine should be discontinued and an autogenous one employed. They believed that they had in this method a safe and efficient treatment of tinea tonsurans, and that the *x*-ray offered no advantages over it.

(*To be continued.*)

AMERICAN NEUROLOGICAL ASSOCIATION.

Forty-first Annual Meeting, Held in New York, May 6, 7, 8, 1915.

PRESIDENT, Dr. GEORGE W. JACOBY OF NEW YORK.

Thursday, May 6—First Day.

Exact and Inexact Methods in Neurology and Psychiatry.—Dr. G. W. JACOBY of New York delivered this address stating that while the rest of modern medicine showed a deplorable inclination more and more to split up into special fields, neurology and psychiatry showed an unmistakable disposition toward amalgamation. The attitude of considering these two subjects as distinct from each other had remained unchanged until the inductive method of investigation had brought experimentation into the field of psychiatry, at which time it had become only too evident how dependent were the psychic functions upon the brain and nervous system. In the light of modern science the bodily as well as the psychic functions were but different forms of the same brain and nerve activity. It was this recognition that joined neurology and psychiatry into one inseparable whole. To be exact, we should speak only of brain and nerve physiology instead of psychology and of nerve and brain pathology instead of pschiatry. The teachings of Griesinger and Westphal had already served to implant and to fixate the fact that the study of mental disease; that is, brain disease could not be managed with any hope of success unless continuous consideration were given to the other diseases that might affect the nervous system. The methods which had given our specialty the greatest successes, and which promised the greatest future progress, were those only which could be recognized as exact and scientific and which stood upon a groundwork of fact. The method of speculative investigation that constructed theories as to how things should be or how things might be from its imagination alone or draw unwarrantable generalizations from single observations must in our work be relegated to the forgotten past. Among the exact methods he counted above all clinical observation, anatomic-microscopic examination of the structures of the body, microscopic examination of the blood and other fluid components of the body. Clinical observation had taught us that in the field of neurology and psychiatry we must learn to individualize. Health and disease were not antagonists; they represented merely different manifestations of the same vital activity. Present day medicine no longer knew the division of human beings into two classes, the healthy and the sick, but dealt only with individuals, no two of whom are precisely the same and each one of whom must be treated in accordance with his own individuality. The author's own experience, covering thousands of blood examinations in cases of nervous and mental disease, in many instances extending over months and embracing a long series of experimental investigations regarding the alkalinity of the blood, had convinced him that their sole value lay in the possibility of recognizing complications dependent upon well known disorders of the blood itself and in differentiating some of the acute infectious processes of the central nervous system as well as in recognizing the presence of some organic basis for affections which upon their face appeared to be a functional nervous character. In his estimation, therefore, the examination of the blood in nervous and mental diseases had been of little value in advancing our knowledge of these affections.

Postnatal Growth of the Brain under Several Experimental Conditions; Studies of the Albino Rat.—Drs. HENRY H. DONALDSON, S. HATAI, and KING of Philadelphia presented this paper. They said that the general results of studies on the rat's brain were applicable to the human brain. Postnatal increase in the weight of the brain was due almost entirely to the enlargement of cell elements already present at birth. The increase in brain weight between birth and maturity was, in the rat, about ninefold. This corresponded to a doubling on the average of the initial diameters of the cells. Increase in size was most evident in the cell bodies of the neurones—but the formation of the myelin contributed more than any other single process to the increase in weight. Under all experimental tests the proportional weights of the divisions of the encephalon remained the same (except in the case of the bulbi olfactorii and flocculi). The conditions under which studies had been made were grouped in accordance with their general effects on brain weight: (1) Unfavorable conditions. Domestication; some defective diets; disease (lung disease). (2) Indifferent conditions. Quantitative underfeeding with wholesome diets; some defective diets; inbreeding; gonadectomy. (3) Favorable conditions. Highly varied diets; exercise. Conclusions and applications.

Dr. L. F. BARKER of Baltimore said that he did not know whether the members of the association realized how much detailed work had been done by Dr. Donaldson and his associates. The results given so briefly were based on a long series of weights and measurements in the animals experimented upon, contrasted with normal weights and measurements established by a long series of observations. It had been Dr. Barker's good fortune to visit the Wistar Institute several times and to see the kind and amount of work that was going on there in connection with the remarkable colony of white rats which Dr. Donaldson and his associates had under their control. The workers were preparing a series of consonants of all parts of the body mathematically accurate for weights and measurements so that when published for the animal we shall have a series of consonants comparable more or less to the tables of the physiological and the chemical laboratory.

The Relation of Structure and Function in the Nervous System.—Dr. STEWART PATON of Princeton said that the first period of life that preceded the incidence of the nervous system as an active factor in the mechanism of adjustment was characterized by a few responses which were primitive in character. Only in the lower vertebrates did we find that any movements of the body took place during this primitive period of embryonic life. We had a very delicate and fairly defined proof that the nervous system was beginning to

play its rôle. We had another important sign, the incidence of neurofibrillation. The appearance of the neurofibrils was probably one of the finest indications that we had of the incidence of function of the nervous system. The heart beats had begun and very probably were initiated without the interference of the nervous system. The heart might be looked upon as an elaboration of a function which existed in chemical functions. As soon as the nervous system came in a great change took place. What did we find in the nervous system at this time? We found something very striking, very striking indeed, something that threw great light on practical neurological problems. In the first place we found out that an enormous preparation had gone on in the whole system preceding the incidence of function. It was really almost startling when one saw the great preparation in the spinal cord and the middle and the upper part of the medulla which had taken place in the differentiation of tissue. The most striking sections found in this region were of the development and persistence of the ancestral type and enormous development of the cranial nerves. Undoubtedly these developments of the cranial nerves were transmitted to us from our ancestors lower down in the scale. Then if we went a little higher up in the medulla there was a very great development of the trigeminus, and in the embryo at this stage you could readily trace three branches coming off from the trigeminus. If we went one step higher in the medulla we would come to the third nerve which had no possible use at this stage of the life of the embryo, and yet that nerve was fully developed. The other point was that if we took this same embryo just before the responses begun we found some very interesting conditions that would interest practical neurologists. We found that such organs as the heart were definitely supplied with neurofibrils. You could trace out the whole cardiac mechanism. In addition to that you would find that an organ like the thymus had an enormous nerve supply. At an early stage, before the reactions of the body began, the thymus had a definite and really an enormous nerve supply.

Dr. James J. Putnam of Boston said that he would like to ask Dr. Paton whether he would be willing to accept all the conclusions to which the view that structure does really and truly precede function would logically lead. It was doubtful whether he would be willing to accept the conclusion that everything we know, learn, and think as human beings, such as love of justice, honor and truth, was really nothing but the expression of structure, which in itself is nothing but the expression of a rhythmical chemical process taken in the usual meaning of that term. It seemed to him that that was the conclusion to which we must come. Either structure preceded function or function preceded structure. From our own observation of ourselves, of thoughts and wills, we would think that function preceded structure. These researches of Dr. Paton's seemed to indicate the reverse.

Dr. Philip Coombs Knapp of Boston said that one simple illustration that structure must necessarily precede function could be brought out from the fact that we were conscious of our functions but were by no means conscious of the structure. The absolute necessity of the structure preceding function was shown by the fact that unless one had a proper visual apparatus he remained blind and never could see. But Dr. Knapp thought that anyone who had had experience in teaching ought fully to realize that it was not the vague transcendental desire to know which accomplished the acquisition of knowledge, but rather the ability of the student to grasp the idea and to develop his knowledge. Experience in teaching showed that in spite of the best developed schemes of instruction, in spite of every desire on the part of the pupil to learn, in spite of every effort of the teacher a certain percentage of the pupils by reason probably of a defect of structure were going to remain hopelessly stupid, a condition against which the teacher would regard himself as powerless.

Dr. Paton in closing said that he had tried to be brief and that in doing so one always ran the danger of becoming dogmatic. He certainly did not intend to bring up the question of education here. Dr. Paton said he was afraid he had made a very bad slip. He had had his guinea-pigs in mind, and as far as guinea-pigs were concerned his statements were true. The criticism was very well taken about the possibility of function preexisting. Of course he had only a few simple reactions in mind which he had succeeded in explaining to his own satisfaction. He thought personally it would be a long time before we got the higher reactions. He hoped his hearers would not take what he had said dogmatically as applied to the human being, and that they would think of him only as an enthusiast in regard to the guinea-pig.

Ventricular Hemorrhage. — Dr. Alfred Gordon of Philadelphia read this paper in which extra and intraventricular hemorrhape were considered. The author reported seven cases of the first and five cases of primary intraventricular hemorrhage. From a pathological standpoint erosions of the walls of the ventricles, rupture of the vessels of the choroid plexus and miliary aneurysm were found in the five cases. Detailed anatomical data as to the state of the ruptured blood vessels and to the surrounding tissue were given. In all the cases profound changes of all layers of the walls of the vessels and especially in the intima were present. In discussing differential clinical features Gordon called special attention to the following symptoms: sudden onset without premonitory symptoms, profound coma at the outset and continuing for several days without improvement, absence of genuine paralysis, absence of rigidity and contracture during the days following the seizure, absence of the toe phenomenon. All these symptoms were so uniformly present in every one of the five cases of primary ventricular hemorrhage that pathognomonic inferences were permissible. In three cases there was a displacement of the brain tissue on the side opposite the hemorrhage. It was possible that the profound comatose state was due to this factor; hence a decompression on the sound side might be of benefit. Accordingly an operation was performed on one case and considerable amelioration of the comatose state was obtained. Unfortunately the other patients did not give their consent for surgical intervention.

Dr. Philip Coombs Knapp of Boston said he had seen a number of cases of intraventricular hemorrhage, most of them, however, of the secondary variety. He could hardly agree with the symptomatology Dr. Gordon had given. In the ordinary symptomatology of the case it had differed very little from that of an ordinary case of ventricular hemorrhage, excepting that the coma had been a little more sudden perhaps and naturally distinctly more profound. In practically every case there had been distinct signs of hemiplegia as we ordinarily detected them in a person who was comatose. The one striking feature, however, in all the cases of ventricular hemorrhage had been that, although the duration of life was too short for contracture to have developed there had been distinct rigidity of both sides. In no case had there been generalized convulsions. In a number of cases confirmed by autopsy he had felt that the rigidity and twitchings of the limbs were so characteristic as to warrant the diagnosis of intraventricular hemorrhage. In every case the signs of hemiplegia had been very distinctly marked.

Dr. Alfred Reginald Allen of Philadelphia said that at Dr. Spiller's instance a number of years ago he had studied in his laboratory the cases of ventricular hemorrhage with particular reference to the rigidity and twitchings and as he remembered the specimen in Dr. Spiller's cases they did not bear out the theory that of necessity there was any relation between rigidity and twitchings and ventricular hemorrhage.

Dr. E. Sachs of St. Louis said that the possibility of approaching these cases from the surgical standpoint must be reserved. It was essential to recognize them, and if they were recognized it seemed to him that it was misdirected effort to do anything but try to approach the hemorrhage itself. To try merely to relieve pressure without trying to remove the extensive hemorrhage which was present seemed to him unwise. He said he had not heard Dr. Gordon mention one symptom which had been described as rather characteristic of ventricular hemorrhage and that was excessive temperature. He had been rather interested in that feature from the physiological point of view. It had been claimed by a number of experimental physiologists that this symptom was due to irritation of the fine fibers that lie along the floor of the ventricle. He had never been able to substantiate that and was rather anxious to hear whether these cases, if they were pure ventricular hemorrhage, showed that symptom.

Dr. H. H. Hoppe of Cincinnati said that in the cases of intraventricular hemorrhage he had seen there was a distinct interval between the onset of the hemorrhage and the condition of coma. In one case there was a period of an hour and a half between the onset of the attack, which resulted from a fall from a horse, and admission to the hospital. In the course of two hours the coma deepened and went on until death.

Dr. E. E. Southard of Boston stated that relative to the hyperpyrexia in the ventricular hemorrhage there were isolated cases in which the rupture of the vessel was of infectious origin. Some ten years ago he had had occasion to report two cases of bacterial apoplexy in which the streptococcus was found; these hemorrhages were from erosion of the vessel wall. The hemorrhage might be regarded as primary in that sense. In one case numerous small hemorrhages were present. He thought that the hyperpyrexia should not be regarded as of chemical origin unless cultures had been taken.

Dr. J. Ramsay Hunt of New York said he would like to ask Dr. Gordon in reference to the condition of the optic nerve, also whether Cheyne-Stokes breathing was present. It was a prominent symptom in a case Dr. Hunt saw. It occurred very early, almost immediately after the hemorrhage.

Dr. Alfred Gordon, in closing, said in reply to Dr. Knapp's remarks with reference to hemorrhage, he would say that as Dr. Knapp had seen only secondary hemorrhages his remarks could have no bearing on the subject discussed which dealt particularly with primary hemorrhage. The five cases of hemorrhage of the lateral ventricles alone were all uniformly accompanied by paralysis, with no toe phenomenon and marked petellar reflex on the paralysed side. In reference to the question of temperature the primary cases had at first no rise of temperature. In secondary ventricular hemorrhage, when coma came on, rise of temperature occurred. As to the optic nerve, every one of the cases was examined and in none was there any change in the optic nerve. Cheyne-Stokes respiration was observed to the very end, but the same in the secondary as in the primary cases.

Intracranial Telangiectasis. — Dr. Ernest Sachs of St. Louis read this paper, reporting two cases, both having Jacksonian convulsions, but no other evidence of intracranial pressure. The eye grounds were normal and the Wassermann reaction negative. In the one case on opening the dura, a huge bluish mass of vessels which were so dense in places that the underlying cortex could not be seen protruded. This mass lay over the motor area. There were no branches connecting with the dural vessels. In the second case the process was entirely confined to the dura, there being connections, however, between these vessels and the cortical vessels. Ligation of all these vessels relieved the symptoms and resulted in a cure. There were a number of cases in the literature which resembled one or the other of these cases, but they had usually been called angioma. A study of these cases, however, had led the author to believe that these were not true angiomata but congenital tumors—telangiectasis. It seemed essential to distinguish between true angioma, a neoplasm, and these congenital conditions. When reclassified they constituted a group which must be kept in mind in every case of Jacksonian epilepsy. The clinical picture was quite a definite one: (1) Attacks of Jacksonian epilepsy occurring at long intervals in non-syphilitic young persons. (2) Unconsciousness of long duration. (3) No evidence of increased intracranial pressure. (4) A very slow progression of symptoms. (5) Telangiectases on the head or face. For this condition the author suggested the name Intracranial Telangiectasis.

Dr. M. Allen Starr of New York thought the distinction Dr. Sachs had made was an exceedingly important one and should be adopted by all means. He had erroneously, as he now sees, reported some years ago as an angioma a case quite similar to the second case of Dr. Sachs. Dr. Starr said he admitted freely that that was a wrong classification and that it was a case of telangiectasis. The case was an interesting one clinically and as it came to operation and Dr. McCosh tied off these vessels it might interest the society. The patient was a boy of seventeen who was brought to the Presbyterian Hospital because he had been suffering from very peculiar attacks for a year. They had begun at the age of fifteen. They were characterized by a sudden severe, intense pain in the pyramidal region on the left side. The pain was located over an area the size of a half dollar. The attack would begin gradually and for three days he was in the most intense agony and the agony was so great that by the end of the second day he was in a state of acute mania. He was entirely uncontrollable, fighting everyone who came near him and these attacks of mania had been increasing up to the time he was brought to New York. He suffered from these attacks in two weeks' intervals. No diagnosis had been made, there were no localizing signs. Between the attacks he was entirely normal in every way. There was no choked disk and the condition was quite a mysterious one. The attacks appeared to resemble in a way attacks of cortical epilepsy, although there was absolutely no spasm. There was an area of tenderness over the skull where he felt pain, which remained between the attacks. Dr. McCosh decided it was worth while to make an exploratory trephining operation. He trephined over the area of tenderness and the dura was apparently normal, but cutting through the dura he came down to one of these conditions of telangiectasis. There was a mass of veins on the surface and they resembled more a mass of fishworms than anything he could think of. The mass was tied off. The boy made a prompt recovery. He had temporarily a condition of complete astereognosis with ataxia of the right hand which after three days passed away. Dr. Starr heard from him two and three years after the operation and he had been perfectly well up to that time.

Dr. Alfred Gordon of Philadelphia stated that in the Proceedings of the Neurological Society of Philadelphia published in *The Journal of Nervous and Mental Diseases* several years ago would be found a description of a case almost identical with that of Dr. Sachs. It was that of a young man of thirty, who for fourteen years, if not more, had had attacks of convulsions in the right leg alone. Never in the arm. The attacks were rarely accompanied by loss of consciousness. The patient could give a good description of the condition. Dr. Gordon examined him a number of times. The eyes were perfectly normal and the knee-jerk over the right side was slight. Dr. DaCosta opened his skull on the opposite side in the upper portion in the area corresponding to the leg center and he found a square shaped appearance of the veins, surrounded by four large veins. The veins were ligated and the patient made a good surgical recovery. He developed a mild astereognosis on the right side and the convulsions ceased for a while. About six weeks later the convulsions returned with loss of consciousness. The patient returned to New York and later on came to see Dr. Gordon again and told him that on exceedingly rare occasions he would have an attack. The condition was exactly the one described by Dr. Sachs. It was a dilatation of the veins in the center corresponding to the leg.

Dr. E. B. Angell of Rochester, N. Y., said he had had a case of Jacksonian epilepsy develop in a youth of sixteen or seventeen. The attacks were so characteristic that it was easy to locate the lesion. He was operated on by Dr. Zimmer of Rochester very successfully. In this case they found the same condition as that described by Dr. Starr. Dr. Angell said that he recognized that it was an angioma according to the description in the books. It was not characteristic of a tumor. He was very glad that Dr. Sachs had given the more satisfactory name for this condition. The case recovered absolutely. The surgeon tied off and removed the veins. For ten years there was no further history of a convulsion.

Dr. J. Ramsay Hunt of New York said that since Cushing's paper a few years ago he had been on the lookout for such cases with intracranial complications. He recalled three cases. One was an old infantile hemiplegia in which there was a contralateral hemiplegia with epilepsy. The other case was that of a man who had a trigeminal nævus and who in his fiftieth year developed epilepsy. The epilepsy, however, was not of the Jacksonian type. It was interesting, however, that always before the attack of epilepsy he would have a period, sometimes several hours, of severe pain directly beneath the trigeminal nævus, so there may have been in such a case a connection between his epilepsy, which was generalized, and the vascular lesion of the dura. In the third case a man had a congenital bunch of veins and all through his life had been subject to periodical headaches somewhat suggesting migraine. He stated that before these headaches these veins would always swell. Of course, the relationship between the veins and the headache was obscure, but Dr. Hunt thought it was always well to bear in mind the possibility of intracranial complications in these cases of trigeminal nævi.

A Contribution to the Paralytic and Other Persistent Sequelæ of Migraine. — Dr. J. Ramsay Hunt of New York read this paper, stating that in the vast majority of cases a tendency to migraine entails no more serious consequences than the recurrence of periodical head-

aches of varying degrees of severity. Headaches of this character are often associated with curious focal symptoms, scotoma, hemianopsia, hemiparesis and hemiparesthesia. More rarely evanescent aphasic attacks and mental disturbances accompany the attack. These focal manifestations are purely functional in nature and disappear promptly with the subsidence of the other symptoms of the paroxysm. They are generally regarded as manifestations of vascular spasm and this theory is in harmony with their temporary and evanescent nature. Attacks of this nature may recur over a period of many years and yet leave no permanent mark or symptom. Unfortunately this is not always true, and in rare cases permanent and often serious consequences ensue. The paralytic and other permanent complications of migraine may appear in various forms, as ocular palsies (migraine ophthalmoplegique), organic hemiplegia with aphasia, hemianopsia, and optic atrophy. At such times there has been frequently noted a marked pallor of the optic nerve and retina, from contraction of the vessels which gradually disappeared with the subsidence of the seizure. Another important and interesting question is the etiological relationship of hemicrania to premature cerebral arteriosclerosis. Some writers maintain that the frequent recurrence of vascular explosions in migraine over a period of many years are in themselves sufficient to cause cerebral arteriosclerosis. The autointoxication which is the underlying basis of the disease is also recognized as a probable contributing factor. It is this combination of factors which would appear to be the important one in many of the cases which have just been described. Another element which must be considered is the possibility of arterial anomalies in the blood supply of the brain and cranial nerves which might render a certain arterial distribution especially vulnerable in the event of sudden vascular spasm. When such symptoms appear in middle life after a migraine paroxysm, especially significant are these symptoms when they are foreign to the usual attack. For example, a migraine accompanied or preceded by transient hemianopsia, when this has been an early and more or less constant phenomena of the attack, would not have the same importance as when this symptom appears suddenly in middle life out of a clear sky. On the other hand, it must be recognized that in just such cases with recurrent scotomata the danger of a permanent defect is by no means a slight one. An importance is attached by some writers to the very doubtful association of migraine with facial paralysis (the hemicrania facioplegica), based upon the contribution of Rossolimo, who described a relapsing facial palsy in conjunction with migraine. This case stands alone in literature and naturally awakens the suspicion of a mere coincidence, namely, the casual association of migraine with relapsing palsy. It is well known that attacks of recurrent facial paralysis are by no means rare and Bernhardt has placed the percentage as high as 7.2 per cent of all cases of Bell's palsy. When it is still further considered that pain in the mastoid and occipital region, often very severe and persistent, is one of the common symptoms of facial paralysis because of the sensory system of the facial nerve, it is evident that the pain of migraine may be closely simulated. Certainly at the present time there is no just ground for recognizing a clinical type of facioplegique migraine in the sense that we accept the migraine ophthalmoplegique of Moebius and Charcot. In passing, it is of interest to recall the observations of Sil, who noted a paralysis of the hypoglossal nerve in a case of ophthalmoplegic migraine. This observation, like that of Rossolimo, is unique and in no sense constitutes a definite clinical type. It is of interest to recall that Oppenheim has described a cerebellar type of migraine in which, with the general symptoms of migraine, there were transient symptoms of cerebellar origin; so that the possibility of permanent lesions in the brain stem and cerebellum having this origin must be kept in mind.

Dr. Joseph Collins of New York said there was one feature of these cases that Dr. Hunt had not mentioned, which he considered to be of very great importance, and that was the syphilitic feature. In a series of 100 cases of syphilitic disorder of the nervous system coming in succession he had found two cases of typical migraine, one of them associated with ophthalmoplegia, in which the evidence of a syphilitic origin was found in the blood and in the cerebrospinal fluid so that he has come now to the conclusion that it is well in the majority of cases of migraine, practically in all cases in which there is paralysis of any sort, to submit to the laboratory tests.

Dr. L. F. Barker of Baltimore said he could confirm Dr. Hunt's observations of hemianopsia with migraine. He has had two cases, one in a lady in middle life. In both of these instances the hemianopsia was temporary, though complete at the time. It passed off and Dr. Barker had not heard from the patients since. In view of what Dr. Hunt had said it was possible that they may later develop hemianopsia. Dr. Barker had made it a routine practice to make serological examinations in all neurologic and medical cases. In neither of these cases, however, had a positive Wassermann been present and in his own experience, while migraine and lues do coexist sometimes, it was not common. He wondered as to the nature of this temporary hemianopsia and thought of a possible temporary lesion in the chiasm and also of a spasm of the occipital artery supplying around the calcarine fissure. His inclination was toward the latter.

Dr. William G. Spiller of Philadelphia said that some years ago Dr. de Schweinitz sent him a patient who had had two attacks of ophthalmoplegia. He had had migraine over many years. His parents had had migraine. Recently Dr. Spiller saw a patient who had had two attacks of transitory ophthalmoplegia. He died two or three years later of an apoplectic stroke. Dr. Spiller said he had seen two cases of hemianopsia with migraine. The hemianopsia is not necessarily a part of the migraine.

Dr. Alfred Gordon of Philadelphia said that several years ago he had had a physician under his charge for periodic attacks of migraine. That man came from a migrainic family. He was about forty at that time and from the age of twenty he had had periodic attacks of migraine. The man had another attack of migraine and Dr. Gordon found him hemiplegic on the right side, astereognosis of right side and motor aphasia. The symptoms were not marked, but they were sufficiently pronounced to observe. There had been increased reflexes, but no toe phenomenon. Preceding the attacks he had vomiting. The eyes were examined and found negative. The patient made a complete recovery and had been well up to the present time.

Dr. P. C. Knapp of Boston said there was one form of involvement of the cranial nerves of which Dr. Hunt had not spoken, namely, the anaesthesias occurring in the distribution of the fifth nerve in connection with attacks of migraine. In regard to the ophthalmoplegic migraine there were a few interesting points to which Dr. Hunt had not referred. In the great majority of them the ophthalmoplegia was an incidental occurrence. The patient had had a good many attacks of migraine before the attack of ophthalmoplegia occurred and after the ophthalmoplegia had occurred they had a good many attacks of migraine without the recurrence of the ophthalmoplegia. In a very few instances there is a fairly regular occurrence of the transitory ophthalmoplegia with each attack of the migraine. The first case of ophthalmoplegia that Dr. Knapp had seen was of that nature. This had occurred in a girl about sixteen years of age. Her first attacks of ophthalmoplegia were of short duration, occurring with the attack of migraine, then the ophthalmoplegia did not clear up with the recovery from the attack of migraine, but remained a partial hemiplegia. There had been found in a considerable number of the cases of literal gradual persistence of the ophthalmoplegia until it became permanent ophthalmoplegia independent of the migraine. The vascular element in the causation of the ophthalmoplegia was, of course, very clear. At the same time it must be borne in mind that in the autopsies of ophthalmoplegic migraine the lesion has not been of a vascular character. There had been either a meningitic disturbance or a tumor in the neighborhood of the third nerve. In regard to the hemianopsia association with migraine, Dr. Knapp had seen two cases.

Dr. N. E. Brill of New York said that only recently a nurse in the training school with which Dr. Brill was connected, who had had occasional attacks of migraine for a number of years, developed a hemiplegia affecting the right arm and leg without any aphasia and without any demonstrable sensory disturbances. The hemiplegia disappeared in three days, leaving the girl rather exhausted. She recovered rapidly and had

an attack of migraine since but no hemiplegia. The hemiplegia in this case was thought to have been of toxic origin.

Dr. HUNT, in closing, said that in regard to the pathology of transient and permanent attacks he personally believed they had the same pathological basis. They were essentially a vascular spasm. Dr. Collins' suggestion of the possibility of lues in migraine was, of course, a very important one. Dr. Hunt would broaden it and say that in a symptomatic migraine with no organic cause it was very important to exclude syphilis. As far as possible he had not done that with the cases reported and regarded them as essential or idiopathic migraine.

Report of a Case of Pituitary Tumor, with Exhibition of Patient.—Dr. WILLIAM M. LESZYNSKY of New York read this paper, in which he reported the case of a boy eighteen years of age. At his twelfth year he began to increase in weight until he now weighed 152 pounds, his height being 4 ft. 9 inches. He had since complained of frequent severe headache, occasional vertigo and vomiting, failing vision, and stumbling gait. There was pronounced adiposity, dry skin, absence of hair in the axillæ and over the pubis, undeveloped external genitals, and tapering hands of infantile type. All of his movements were slow. He yawned frequently, and then fell into a deep sleep, unless aroused. There was retarded mental development corresponding with the Binet scale for the twelfth year. The *x*-ray picture showed erosion of anterior clinoid process and calcareous changes in the floor of the sella turcica, which was not enlarged. In the right eye the vision was diminished to perception of light; the left, equals 20 100 with contracted fields for form and colors. Bilateral primary optic atrophy. Exaggerated knee jerks, ankle clonus and Babinski plantar reflex. Blood, cerebrospinal fluid, and urine negative. Increased carbohydrate tolerance. The intracranial pressure symptoms were attributed to internal hydrocephalus. The visual disturbance was assumed to be the result of pressure upon the optic nerves, either from a distended third ventricle, or from a hypophyseal tumor. The corpus callosum was punctured, in order to establish permanent subdural drainage. Ten days later all of the symptoms of intraventricular pressure had disappeared. He had since remained in good health and one year after his discharge from the hospital the vision had improved to shadows at 3 feet with the right eye and 20 40 with normal fields in the left eye.

Dr. E. B. ANGELL of Rochester said he had had two of these cases the past winter and was really somewhat in doubt as to what to do with them. He saw Dr. Cushing perform one of his transsphenoidal operations and made up his mind that it was paying a high price for getting a little improvement. If this treatment followed by Dr. Leszynsky was satisfactory it would certainly be a big gain.

Dr. ERNEST SACHE of St. Louis said he thought it was extremely important in the study of these questions to understand the directions in which the pituitary tumor was growing. They had found it absolutely essential in all pituitary cases, in fact in all intracranial cases, not to be satisfied to pass judgment on *x*-ray findings unless they had a stereoscopic picture. They found when they studied these stereoscopic plates that they got a very different picture. He felt that corpus callosal puncture in general did not offer a very effective means of relieving a hydrocephalus.

Dr. W. G. SPILLER of Philadelphia said the question which Dr. E. Sachs had brought up was a very interesting one. He had recently a case in consultation with Dr. Frazier and Dr. de Schweinitz where it has come up. Could we be sure that the hydrocephalus was caused by the pituitary tumor or the pituitary symptoms caused by the hydrocephalus? Dr. Spiller was of the opinion that hydrocephalus may be primary and by pressure on the pituitary body give the symptoms of pituitary tumor. In the case referred to, a child of 10, with marked pituitary symptoms, increased sugar tolerance and eye symptoms callosal puncture was done with relief of ocular findings, but no relief of general findings.

Abderhalden Reactions and Defective Mental and Physical States.—Drs. S. D. W. LUDLUM and E. P. CORSON WHITE of Philadelphia said that regardless of the criticism of the Abderhalden reaction they again joined the group which saw fit to defend it. In the blood of a thymectomized dog they obtained reactions to testes and pancreas, just as had previously been done in patients which had physiological symptoms of thymectomy. Following this they saw three cases of backwardness in children in which the symptoms were those of lymphatism. These cases reacted to thymus. Results of treatment of these cases with pituitary extract were phenomenal. A girl of 5 years showing gigantism reacted to pituitary. The symptoms were controlled by thyroid extract. They had ten cases of hypomaniac state in adults pointing to hyperpituitarism rapidly controlled by the opposite harmone. A case of infantilism which reacted to thymus started to grow when put upon pituitary extract.

Dr. HENRY A. COTTON of Trenton, N. J., said that this was the most important problem before the psychiatrist. The question of the influence of the ductless glands or the glands of internal secretion upon mental conditions, probably more especially in dementia præcox, seemed to be evident to-day. It seemed to him the work they had been doing in Trenton in the last two years in regard to dementia præcox was supporting in another manner the question of glandular affections connected with this disease. Following out Cushing's ideas in hypopituitarism they examined a number of cases. They examined the blood pressure, sugar tolerance, the polyuria, and all of these cases have shown one thing, that is that the pituitary gland was at fault. There was probably a group of cases in which the thymus was affected and perhaps the suprarenal and the other glands also. As these studies were developing we could at least look to some definite facts to be gotten out of this work to indicate a proper theory.

(To be continued.)

WATER IN THE PREVENTION AND CURE OF TUBERCULOSIS;

WITH A PLEA FOR PUBLIC BATHS FOR OLD AND YOUNG AND SWIMMING POOLS PARTICULARLY IN CONNECTION WITH PUBLIC SCHOOLS

BY S. ADOLPHUS KNOPF, M.D.,

NEW YORK.

PROFESSOR OF MEDICINE, DEPARTMENT OF PHTHISIOTHERAPY, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

BECAUSE hydrotherapy in the treatment of tuberculosis, and particularly pulmonary tuberculosis, is, in my humble opinion, next in importance to aerotherapy, and because it is relatively little used even in some of our otherwise well equipped sanatoria and by some well trained phthisiotherapeutists, I have gladly accepted the honoring invitation of your president, Dr. Simon Baruch, who may justly be called the father of hydrotherapy in this country, to present this short paper on the use of water in the prevention and cure of tuberculosis.

Before speaking of the external uses of cold water, I wish to say a few words on the internal use. If one is in the habit of taking a careful anamnesis of a tuberculous patient when he presents himself for the first examination, and does not fail to inquire into the condition of the patient's bowels, the examiner will discover in a very large percentage of cases that the patients are habitually constipated. As a matter of routine, I invariably ask the new patient how much water he drinks daily; most frequently the answer is "I drink very little." When the patient is taken under treatment and urged to drink from six to eight glasses of water between mealtimes and even small quantities with his meals, it is surprising to notice how quickly nearly all the symptoms, such as constipation, high temperature, headaches, malaise, and anorexia disappear, and even the cough becomes much better. Of course, the explanation for this improvement lies in the fact that with the increased ingestion of water the toxins secreted by the tubercle bacilli as well as the toxins from an overloaded intestinal tract, become largely diluted. The temperature is lowered, the bowels evacuate freely, the kidneys excrete more abundantly, thanks to the increased amount of liquid, and a feeling of relative comfort replaces that of nausea, malaise, headaches, etc. The increased amount of water ingested also helps to make the sputum less tenacious. This beneficent action of water on cough and expectoration can be materially increased by urging the patient to take an abundance of salt with his meals. Aside of the well-known fact that by the ingestion of chloride of sodium the demineralization characteristic of tuberculous individuals is counteracted, the salt and water produces an increased osmosis, facilitating cough and expectoration. Permitting the patient to take a moderate amount of liquid with his meals and urging him to take a glass of cold water instead of a cocktail before his meals often has a surprisingly good effect in improvement of appetite, general nutrition, and consequent increase in weight.

The old superstition about not taking any liquids with meals is still ingrained in the vast majority of even intellectual people. They forget that a moderate quantity of water ingested with a meal helps instead of hindering digestion. The belief in an aperitive, the alcoholic appetizer commonly called a cocktail, as a means to increase the appetite and stimulate digestion, is even strongly implanted in the minds of some physicians, if we are to judge from the dinners which we are occasionally privileged to attend. That a glass of clear, cool water, taken half an hour before meals, is the best appetizer and stimulant for the gastric secretions, is a gospel which needs to be spread and practised a little more freely and a little more ardently by medical men.

When the patient in the latter stages of tuberculosis is feverish, next to rest and fresh air the ingestion of cold water (pure, in lemonade, or as cracked ice) or ice cream with the external hydrotherapeutic applications, is the best antipyretic remedy at our disposal.

Now let us turn our attention to the external use of cold water which is invaluable as a prophylactic and curative means in tuberculosis.

If I should be asked to define predisposition to tuberculosis either inherited or acquired, I would briefly answer that it was physiological poverty. All that should be and is physiologically rich in the normal man is physiologically poor in the individual predisposed to tuberculosis. His circulation is deficient; he is anemic, that is to say poor in blood; his nervous system is easily exhausted; he tires easily, and his muscles are flabby—all of which indicates a poor assimilation of food; his skin shows the same characteristics as the muscles and is very sensitive to changes of temperature because of its deficient contractility upon the small blood vessels which it contains; in other words, the whole cutaneous, muscular, and nervous systems are below par.

The value of the internal use of water, of which I have just spoken, is as great in the predisposed as in the typical tuberculous invalid, but there is perhaps no remedy of such inestimable value to overcome the above-mentioned physiological poverty as the external use of cold water. We know, of course, that the mechanical and thermic stimulations of the skin are responsible for the effect of

*Read by invitation before the American Association for Promoting Hygiene and Public Baths. New York, May 11, 1915.

cold water (75° to 60°) on the normal system; we know that even the exposure of the body to cold air brings about the same stimulating effect through an increase of oxygen consumption in proportion to the intensity of the cold. The cold water has the same effect, but in addition, particularly when taken as a shower bath or spray, it produces an invaluable mechanical stimulation.

The predisposed individual who, as I have already stated, because of the lack of contractile power in his skin, is sensitive to the unwholesome influence of sudden changes of temperature and non-resistant to the invasion of germs of influenza or common colds, will find the very best prophylactic measures in the judicious use of cold baths. Hence I cannot plead too ardently for the establishment of public baths, municipal, and others, including floating baths for the warm season; but they should all be supervised by the proper health officials. Let bathing in winter and in summer be made not merely an act of recreation, but one of the essential features to develop a healthy, strong, and tuberculosis-free population. If the town is situated near the sea coast, salt water from the ocean should be utilized to the largest possible extent for such public baths. All public baths, be they maintained by the municipality or by private individuals, should of course be properly constructed and they should be so supervised that the propagation of infectious diseases shall be impossible and drowning and other serious accidents shall be guarded against.

In advocating public baths so ardently, I do not however wish it understood that I am not strongly in favor of every family living in city or country having its own bathroom. To judge from my early experience as a poor student, bathrooms are rare and far between for the young man or woman obliged to live in a boarding house or cheap rooming house, and I would suggest a means whereby these people, often alone in the world, could also enjoy the luxury of the exhilarating and health-giving influence of a daily cold bath.

With the aid of an English bathtub, or collapsible rubber tub, 7 to 10 in. deep and about 3 ft. in diameter, a small watering pot with a spout, and with a little ingenuity one can establish a very simple but effective shower bath. Not to get into conflict with the landlady, the tub can easily be placed under the bed when not in use and the floor may be protected against getting wet by a large piece of oilcloth. In winter the room in which the bath is taken should be comfortably warm.

The physiological effect of cold water on the body has been so often and so well described that I feel I could only reiterate what has been said by others much better than I have the time to do here, nor do I feel that I have the ability even if I had the time.

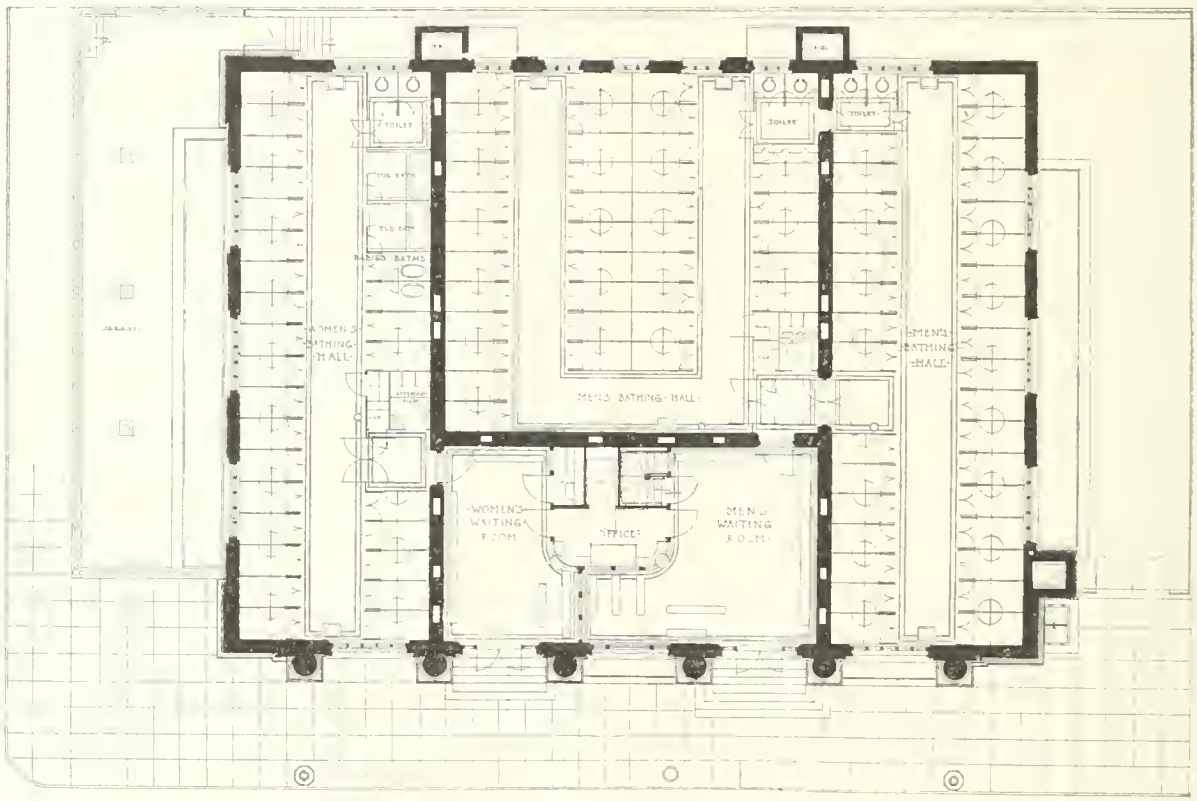

Fig. 1.—Plan of first story of the public bath located at Montgomery and Charlton Streets, Newark, N. J.

Baruch* puts it very tersely in the following sentence: "The nerve endings in the skin furnish a clew to that remarkable sensitiveness of the epidermic layer which opens to hydrotherapy a free gateway to the central nervous system, and especially to the sympathetic, which controls most of the organic functions.

Geyser† describes the tonic effect of cold water on the tuberculous invalid in the following words: "In them the mechanism of the leucocytic and erythrocytic apparatus that should produce antiferments against the tubercle germ is altogether absent, or is devitalized and minimized in efficiency. Tuberculosis and anemia are almost inseparable. Such a

†Geyser, Albert C.; "Water as a Physiological Tonic." *New York Medical Journal*, Vol. CI, No. 21.

patient requires tonic treatments; he is in urgent need of something that will start his cytogenic apparatus into full activity. There are three very important things that will do this, viz., proper food rich in fats and carbohydrates, scientifically

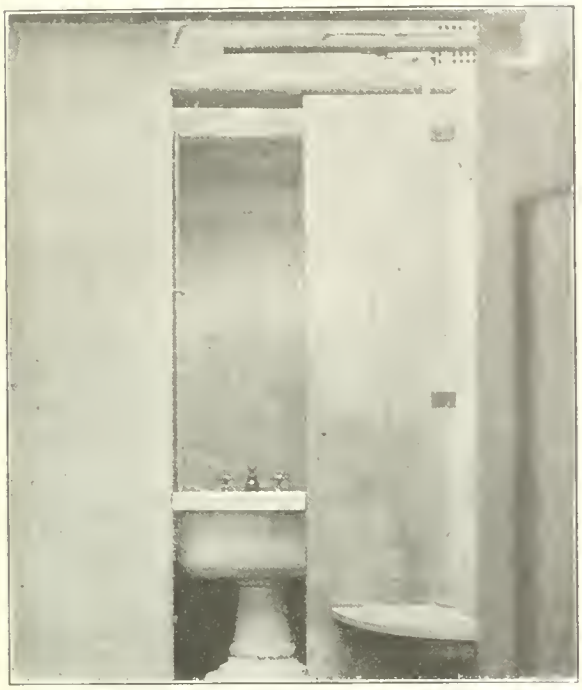

Fig. 2.—The public baby bath.

regulated exercise of body and special breathing exercises, and the tonic effect of the cold baths. All these are at once followed by an enormous increase in red and white corpuscles. Greatest among these is the cold bath at 76° Fahr., taken upon rising in the morning."

If prior to my taking up tuberculosis as a special study I had any prejudice against the external application of cold water to phthisical patients, it was soon overcome when I had the privilege of serving as assistant to the immortal Dettweiler in the Falkenstein Sanatorium for consumptives. In this latter, though a private institution, the patients were most obedient and willing to submit to whatever therapeutic measures were prescribed for them. It was a surprise to me then to see nearly all the ambulant cases line up every morning for their cold shower in the hydrotherapeutic establishment. Most of the patients took a short walk before their douche to get what the French call a preaction.

My observations of the hydrotherapeutic method then in use at Falkenstein, however, did not wholly satisfy me. I could see much good from its use in some cases but not in others, and I thought the application of water in the treatment of phthisis should be much more individualized, especially in a sanatorium. In a goodly number of cases I could see that the inspiration gradually deepened, that the heart contracted better, that the superficial cutaneous hyperemia caused by the cold water relieved the congested pulmonary condition, and that concomitant with this there seemed to be a general improvement in the nutrition. It seemed to me, however, that a number of patients, although they imagined they had reaction, did not really react, and with the exception of purely incipient cases I am to-day convinced that in phthisical patients the routine application of cold water in the form of douche or rainbath can be productive of a great deal of harm.

For the incipient cases who react well and who can go to the hydrotherapeutic establishment in the institution I recommend a short walk, or calisthenic exercises before the douche, but neither the walk nor the physical exercises taken before the bath with the view of producing a good reaction should be of such a nature as to cause the patient to become over-tired. The temperature of the cold application may range between 80° and 70° Fahr.

Geyser maintains that "a drop of 22° applied suddenly over the entire body is sufficient to arouse all the physiological functions." Personally, however, I have found that 5° more or less matters very little in the application of cold water for the average incipient case.

There are, of course, cases even among the incipient in which it is necessary to begin with much higher temperatures (95° to 90° Fahr.) until the patient's cutaneous and nervous systems are sufficiently hardened to stand lower temperatures (80° to 65°). The duration of the application of the cold water should likewise be graded and be short at the beginning; in some cases thirty seconds to two minutes is all that should be attempted at first.

No elaborate apparatus is necessary. An arrangement which enables a direct jet of water to fall with moderate force from above on the patient's shoulders and a horizontal bar which he can take hold of so as not to slip is all that is necessary. The patient himself makes the apical regions of his chest the recipients of the jet of water alternating the right and left sides and preventing his head

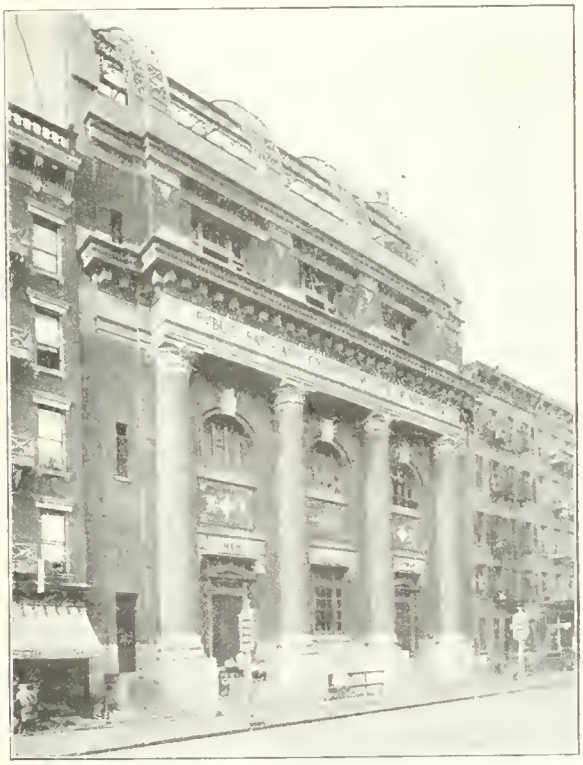

Fig. 3.—Public bath and gymnasium.

from getting wet. If he cares to he can place himself so that the stream of water will strike his sternum and spinal column. The whole body is thus quickly bathed and he enters a moderately warm room where he may dress.

One may of course also take the tonic bath by complete immersion up to the neck in the ordinary bathtub. In this case also the temperature of the water should be regulated (95° to 75° Fahr.) and so should also the duration of the bath (1 to 3 min.), according to the condition and reactive power of the patient. When the patient takes his cold bath in this way the bathroom should be warmed to a temperature of 80° to 85° Fahr. and warmed rough towels should be at hand for the patient to use himself or his attendant to give him a vigorous rubbing over the whole body for several minutes. The patient should then put on a warm bathrobe and return for a few minutes to the nearby warm bed, unless he does not feel tired at all and is warm enough to dress.

Whether the bather is merely predisposed, incipient, or in the early stages, if he has no pleasant feeling of warmth after the application of the cold water, either the water has been too cold, he has exposed himself too long, or his cutaneous surface and nervous system have not been sufficiently trained to withstand the shock. To avoid unpleasant complications which might arise from this lack of reactive power, the patient immediately after the bath should be placed in a warm bed adjoining the douche room and a glass of hot millk or hot lemonade administered.

The vigorous rubbing of the entire body with a well warmed and pretty rough towel is one of the best means to assure a reaction.

Perhaps the vast majority of patients which come under our observation have not been in the habit of using cold douches or cold baths, and if they have been fond of cold bathing or cold showers prior to their becoming ill, they have ceased using them with the beginning of their tuberculous illness. These patients must be reeducated to the use of cold water and the physician who succeeds in doing this will invariably be repaid by most gratifying results.

Let me state here briefly the very simple method to which I resort to train the untrained patient to the use of cold water and to assure reaction. It is the chilling which the patient himself fears and the physician ought to fear, that demands our attention, and we must avoid it. Thus, I believe it is best to have the patient take douches either in the morning when arising from his warm bed, or in the evening after he has been in bed for about half an hour and has become thoroughly warm. If necessary, the bed can be warmed with the aid of a hot water bag which may remain at the feet of the patient.

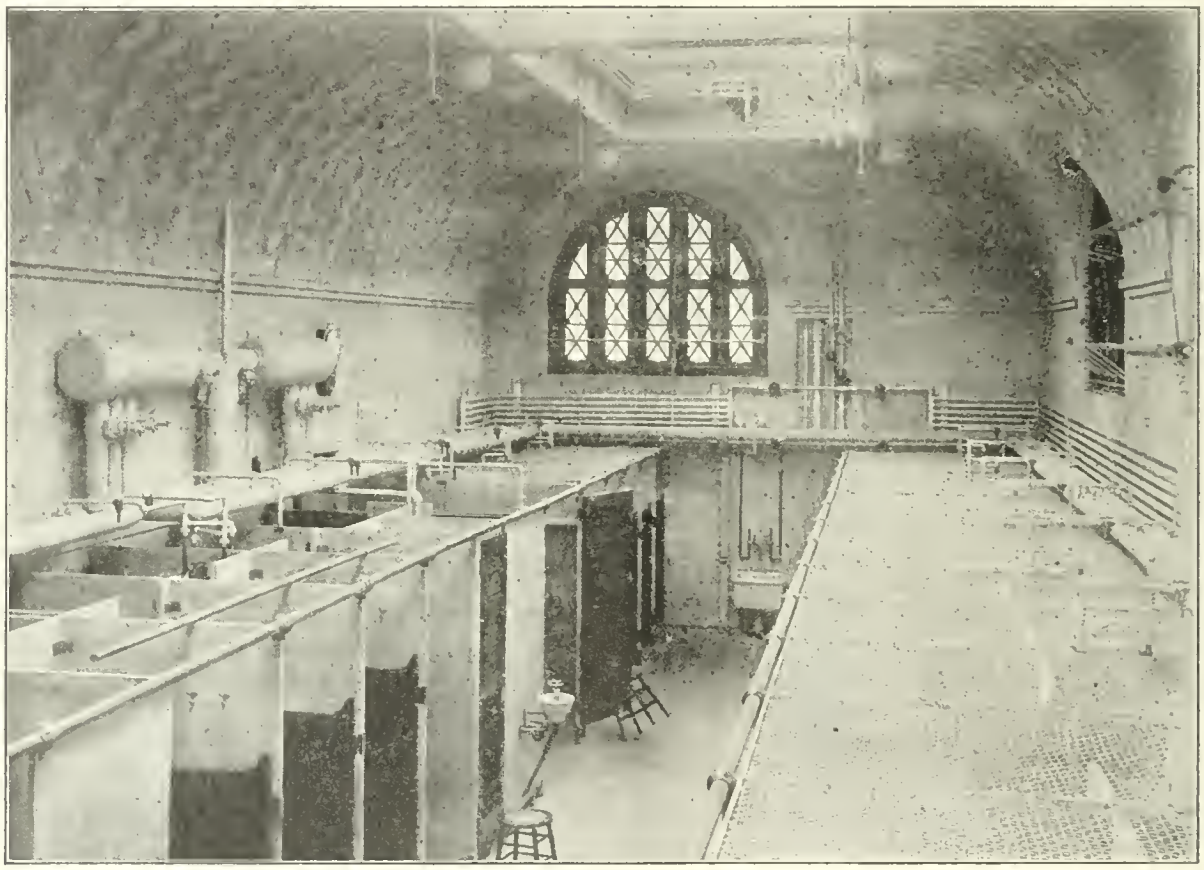

Fig. 4.—Public shower bath

It is also of greatest importance when good reaction is not certain to place the hydrotherapeutic outfit as near the bed as possible. To this end I recommend a circular English bathtub, perhaps a little larger than the one already referred to above. Moderately hot water (about 110° Fahr.) is poured in to the depth of about 5 in. The patient then rises from his warm bed, divests himself of his night clothes, which he places in the bed, covers the latter so as to retain the warmth, and steps into the warm water. Then a second person pours one or two pitcherfuls of cold water quickly over each shoulder, thoroughly wetting the whole body. The head should not be wet.

The douche can, of course, be taken more easily with the help of a second person to pour the water from a pitcher or water pot, but it is possible for the patient to do it himself. If a hose can be

attached to a nearby faucet, a douche, bath, or direct jet can be improvised.

If the patient prefers, or is obliged, to attend to the douche himself, he should proceed as follows: Place the English bathtub or a larger washbowl with hot water in it on the floor to stand in and have a smaller washbowl filled with cold water and a good sized sponge placed on a table within easy reach. While standing in the larger bowl, or tub, squeeze out the sponge soaked in the cold water once over the left shoulder, once over the right, once in front of the neck, and once over the back of the neck. Thus the whole body will be douched. The patient dries himself partially so as not to wet the bed too much and returns quickly to the latter. Under the warm cover he will feel warm and the little moisture on his body, if there is any, will soon dry. He then puts on his nightshirt. Through this procedure reaction is assured and the patient rarely fails to enjoy the douche and to feel comfortable after it.

The temperature of the cold water can vary from 80° to 65° Fahr. For timid patients, or those who have never used a cold douche or have not used one for a long time, it is wise to begin with the hydrotherapeutic application at a temperature of 90° or 85° Fahr., or 95° and gradually go down to 65° or whatever temperature the water may be, as it comes out of the faucet. Of course it must be borne in mind that for example in New York City in midsummer, where the temperature of the water coming out of the faucet may range from 70° to 80° Fahr., it will be necessary, in order to have a temperature of 65° to add some ice water to lower the temperature to the desired degree.

From what has been said thus far about the application of cold water as a tonic and to invigorate the tuberculous, it must be evident that individualization is most essential. A routine hydrotherapeutic treatment for the consumptive may prove as disastrous as a routine aerotherapeutic, solartherapeutic, dietetic, or routine symptomatic treatment.

It is always well to have the windows closed and the room warmed while the douche is being taken. If in spite of all these precautions the patient should fail to react, the douches should be discontinued and only resumed after the general condition has improved and enough weight and strength has been regained to assure reaction. If during the application of cold water the head should accidentally get wet the hair should be thoroughly dried. This precaution the patient should always bear in mind whenever he has washed his head.

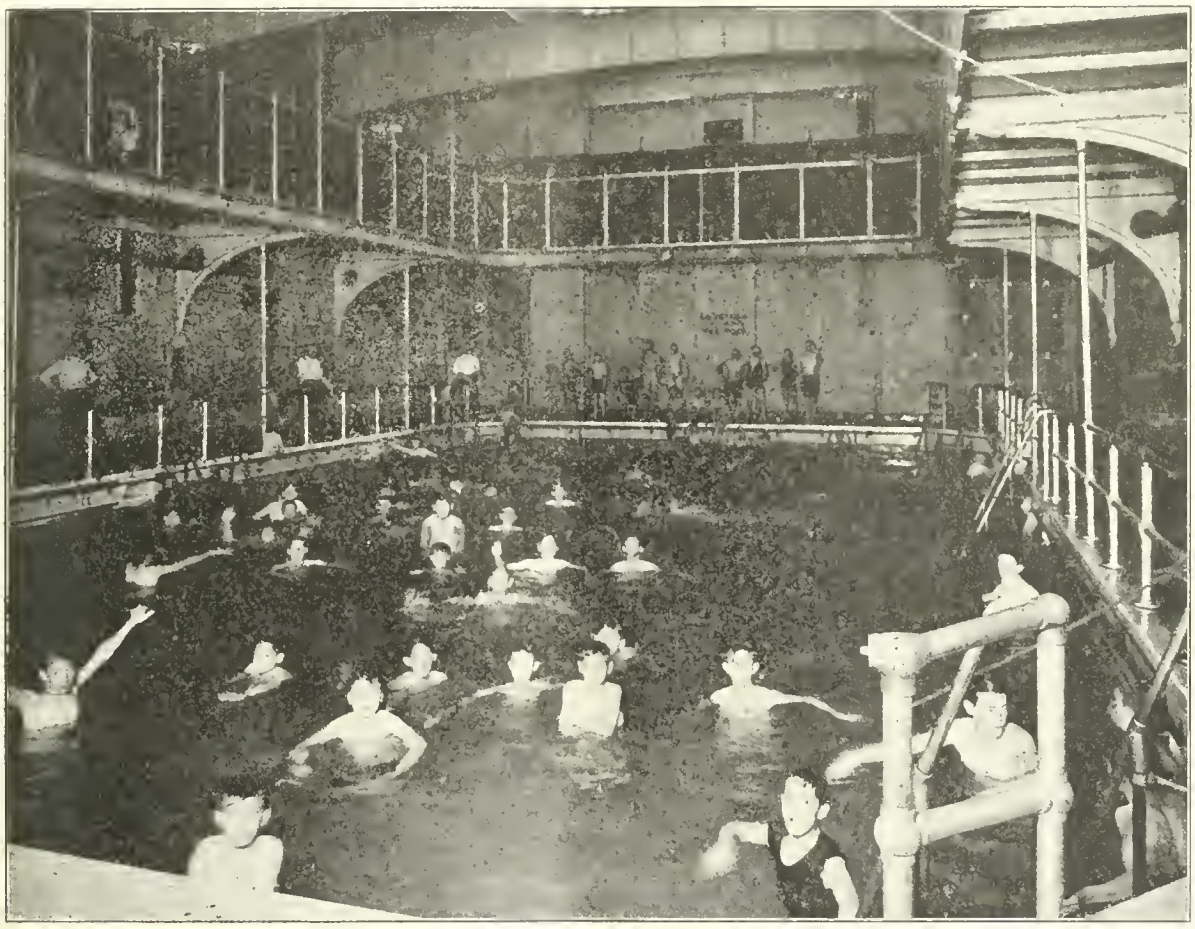

Fig. 5.—Swimming pool in one of the New York public baths.

There remains now only for me to say a few words on the application of cold water in the symptomatic treatment of pulmonary tuberculosis. Sponging the patient with three-fourths water and one-fourth vinegar will materially aid in the combat of hyperhydrosis. To combat obstinate night-sweats, distinctly pleuritic pains, intercostal neuralgia, and uncontrollable cough, I have found the wet-pack equally good. With the aid of three towels or several thicknesses of rather coarse linen, one for each apex like a broad shoulder strap, and another wider one to wrap around the chest, an excellent wet-pack can be arranged. The three towels or the three pieces of coarse linen are soaked

in water at a temperature of about 50° Fahr., wrung out rather hard, and then applied over the apices and around the thorax. A thick flannel band, somewhat wider than the compress, is wrapped over this and the whole fastened in place with safety pins. The patient usually feels no discomfort as a result of this application, sleeps well, sweats but slightly, and pleuritic and intercostal pains often disappear like magic.

The external application of water as an antipyretic remedy in tuberculosis is of course all important. As a rule, we may say the weaker the patient and the higher the temperature, the more decidedly tepid should the water be (85° to 75° Fahr.). For the average patient sponging off —first partial, then entire—with water varying from 65° to 55° Fahr. is indicated. With timid patients the sponging off should always be gradual and partial at the beginning, and in the following order: hands, forearms, face, throat, neck, armpits, arms, back, stomach, gluteal regions; finally, the lower extremities from the hips downward. This sponging off should be done under cover, and with as little exposure to the air as possible. Each portion, after being sponged off, should be rapidly covered without being dried, so that the gradual evaporation of the water adds to the cooling effect. The effect of the first application will be a guidance to the physician for further procedure. This method of applying the cold water can be repeated three, four, or more times daily until a perceptible reduction in the temperature is attained. In the use of wet-packs the same gradual procedure and the same care as to the temperature should be exercised.

I do not favor the entire enveloping of a phthisical patient in a cold sheet for the reduction of temperature, but prefer the partial application of compresses to either lower or upper extremities or the compress over the chest, already described. I resort to this especially when the sponging off seems to disturb the patient too much. I apply the wet-pack first for a while to the lower extremities; next to the upper, and so on alternately every half hour. The wet-pack can also be improvised with the aid of a couple of ordinary towels as pack and a few larger Turkish towels as cover. When the temperature is very high an ice bag over the heart will render excellent service; but still better is the application of a coil of rubber tubing over the head or over the heart. The water can be made as cold as desired, and the rubber coil is not nearly as heavy as the ice bag and more easily applied.

In conclusion, permit me to say that all I have endeavored to do is to show briefly the great value of the judicious use of water as a prophylactic and therapeutic agent in tuberculosis. As I have said so many times, it is my humble opinion that hydrotherapy is only second in importance to aerotherapy in the modern treatment of pulmonary tuberculosis. However, since the future of medical science will lie in preventive measures and your association stands for the promotion of hygiene and public baths, I ask to be placed on record as saying that well conducted and carefully supervised public baths, which will be opened to the masses all the year around, will be one of the most important factors in preventing the diseases of the masses, of which, alas! up to this time tuberculosis is still the foremost.

I would consider my paper incomplete did I not in conclusion say a word about the inestimable value of the external application of cold water in the prevention of tuberculosis in childhood. I consider that for the average child cold water application is permissible after the age of one year. Of course, one must not think of plunging the young child in cold or even cool water. But every mother or nurse after she has given the child its warm bath can with safety put her own hand in pretty cold water and then apply it to the child's body, repeating this operation a few times until the whole of the child's body has been touched with the cold water, the temperature having been modified and reaction assured by the mother's or nurse's warm hand and gentle friction. This method carefully applied will prevent the child from so-called colds perhaps more than anything else. There are few children who do not thoroughly enjoy this little finish of their daily bath.

By a wise philanthropy the city fathers of Newark, N. J., have upon the suggestion of Mrs. Mary E. Jacobson of that city incorporated in the recently completed public baths facilities for bathing babies (Fig. 1). The poor mothers who have no bath facilities at home can take their babies there and give them their daily baths under the best sanitary conditions. The accompanying picture (Fig. 2) is an illustration of the public bath baby.

As the child grows older, the temperature of the cold application can be decreased and the duration correspondingly increased. When the child arrives at school age, particularly the city child from the overcrowded tenements, I trust that it surely will get into a school where there are shower baths and swimming pools. I cannot plead too ardently for both—for the cleansing bath because it prevents disease in school and at home, and for the swimming tank because of its invigorating, health-giving, mind and body cleansing, and life-saving effects.

When I say mind as well as body cleansing I do it advisedly. I have it on the authority of eminent pedagogues that the children who have the advantage of shower or better yet swimming baths in public schools do better work, are mentally more alert, and are better behaved than pupils who have not had this privilege. When the boys and girls have become accustomed to bathe at the school they exert a beneficent missionary influence on their parents, who are often full of prejudice against the baths, which cannot be overestimated.

Concerning the life-saving effects of the swimming pool for children I cannot speak too feelingly. It is my privilege to be the senior visiting physician to the Hospital-Sanitorium for the Consumptive Poor of the City of New York, known as the Riverside Hospital Sanatorium for consumptives, located on North Brother Island. I believe you all remember that fearful catastrophe known as the Slocum disaster. I was on duty in the hospital, when on the morning of June 15, 1904, a boat laden with 1500 happy people, mostly women and children, came up the river. It was an excursion party from St. Mark's Lutheran Church. Just before reaching North Brother Island the boat took fire, the captain made a heroic effort to reach the island; the boat was beached only a short distance from the hospital. The usual panic ensued, and a struggling mass of humanity, some with and some without very defective life preservers, jumped or were thrown into the water. Physicians and patients from the hospital went into the water and saved as

many lives as they could. The water was shallow near the shore and had these women and children known how to swim, instead of more than a thousand lives, of which 900 were children, none or perhaps only a few would have been lost.

Aside from the invigorating, the healthful, and buoyant feeling which a swim in clean pure water gives to the bather, I maintain that to know how to swim is necessary as a life's equipment for every man, woman, or child. All public schools have fire drills to prevent the loss of life in the event of a fire. It is equally important that the children should know how to save their lives and perhaps those of others by knowing how to swim. I plead that swimming lessons be made a part of the curriculum of every public school. To have seen more than 900 little bodies laid out on that terrible day on North Brother Island made an impression on me which will last forever, and as I have often been before so today am I grateful for the opportunity to plead for public swimming pools, particularly for our school children. The money a municipality invests in public baths, floating baths, seaside baths, and swimming pools will give splendid returns in the saving of lives—directly and indirectly. Indirectly by making people clean physically and morally, by preventing disease through the cultivation of cleanliness, and by making the people more vigorous and thus resistant to the invasion of disease. Directly by teaching every future citizen, man or woman, how to swim and to save his life in the event of accident.

That the bathing establishments can be made ornamental as well as useful, the city of New York has already shown. Through the courtesy of Messrs. Werner and Windolph, architects of a number of them, I have come into possession of some plans and pictures of such baths which I herewith reproduce. Figs. 3, 4, and 5 represent one of the latest New York public baths, including gymnasium and roof playground. I hope the sight of these illustrations may stimulate city fathers and philantropists everywhere to become advocates of one of the best methods to improve health and give pleasure and recreation to old and young throughout the community. Nor should we confine ourselves to public baths to be used all year around such as are pictured here. We should also encourage the establishment of public swimming and bathing facilities on seashores and in rivers and lakes wherever the latter two are not used as drinking water by the community and are not contaminated by sewage.

Hence, I sincerely hope that the present agitation for an increased number of floating baths in our own city will meet with success. Every one who has made a study of the situation will agree that there is urgent need of such floating baths during our hot season.

I deem it indeed a great privilege to have been invited to address a body of men and women who, like you, are such ardent advocates of all such institutions as I am pleading for with all the ardor and earnestness I am capable of. All lovers of their kind, all true statesmen, city fathers, and physicians hail the work of your association and wish you Godspeed in your noble endeavors.

A STUDY IN BLOOD COUNTS IN RELATION TO VACCINE THERAPY.

AUTOINOCULATION IN THE TREATMENT OF MOUTH INFECTIONS.*

By JOSEPH HEAD, M.D., D.D.S.,

PHILADELPHIA.

During the last year, as in previous years, vaccines have continued to prove of great value in the treatment of mouth infection. Advanced cases that ordinarily would drag along with local treatment alone or which would make a gradual progress only to lose ground when treatment was suspended, under a well-chosen vaccine would yield to treatment in three or four months, and the progress would continue with unchanging impetus for a period of a year or two.

It must, however, not be forgotten that vaccine without effective surgical treatment can be of little service, for if the depots of infection are left in the mouth, the curative effect of any vaccine must soon be overcome and the patient will certainly relapse into the original septic condition.

But this paper was written to show the value of blood count in the use of vaccines. I have here for your consideration some blood charts that may prove of interest. They represent some cases where vaccine was given and some cases that were presumably normal. Without going into these cases specifically I might say that blood counts have taught me to be more moderate in my dosage, and I have found that my patients have responded at least as well, if not better, than when the doses were pushed to the point of getting marked reactions. In one case

*Read at a meeting of the American Association of Immunologists, Washington, May 10, 1915.

Fig. 1.

a man of forty without any external symptoms developed a leucocytosis of 71,500 in one week, shooting up from 13,000. His vaccine contained per cubic centimeter: Staphylococci, 300 million; mixed streptococci and pneumococci (4), 50; gram negative bacillus, 50; Gram negative cocci (3), 50; Gram positive bacillus (2), 50.

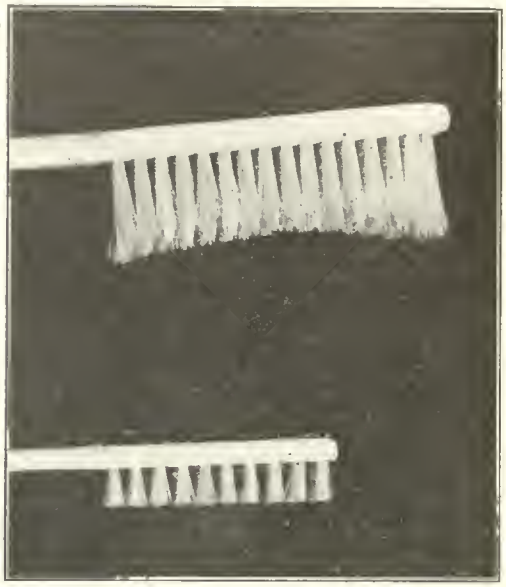

FIG. 2.—Toothbrushes, correct and incorrect; three-quarters actual size.

It was started at 1/10 c.c. and advanced each week 1/10 of a c.c. There were no symptoms except rapid healing of the gums on the sixth dose, when he had 8/10 of a c.c. His leucocytosis, as before stated, went from 13,000 to 71,500.

In another case a patient showed during the treatment a variation in hemoglobin from 65 to 48 per cent, while the leucocytes varied from 16,000 to 8000. A vaccine was given her containing per cubic centimeter: Gram negative bacilli (2), Gram negative cocci (2), streptococci (2), 50 million of each. She was given 1/10 c.c. for three times a week apart, the only reaction being a slight fatigue, and later on there was not even this physical symptom. After the third dose her blood count showed microcytes and a few poikylocytes, and the dose was reduced to between 1/30 and 1/50 c.c., making for the streptococci one to three million and the other germs in proportion. I only mention this case to show that without the blood count injury might unquestionably have been caused this patient by excessive dosage. In other cases the erythrocytes and hemoglobin dropped and the leucocytes rose rapidly on the first dose. Here again we had a warning to reduce the quantity of vaccine and not to increase it until the blood seems to stand the strain put upon it.

The Arneth counts, according to my record, have shown a persistent tendency for the division of two nuclear segments to exceed in percentage that of the division of three nuclear segments. The two segments varying from 45 to 60 per cent, while the division of three segments, instead of being 33 to 48 per cent, according to Simons, was ordinarily between 15 and 30 per cent. Lymphocytosis does not seem to be as much of a factor as I thought last year. The lymphocytes ordinarily do not go up to 40 per cent—usually being nearer 20 and 30 per cent.

In counting the number of erythrocytes and leucocytes a single Thomas Zeiss pipette was used. The blood was drawn to the mark 0.5 in the pipette and the pipette was immediately filled with Toisson solution to the mark 100. A Turck counting chamber was used and it was filled twice for every case; 288 of the large squares were always counted for the leucocytes and 200 of the small squares for the erythrocytes. For the estimation of hemoglobin the Dare hemoglobinometer was used in every case, as was also the Tallquist hemoglobin scale. The latter, however, was not found to be sufficiently accurate. The Dare hemoglobinometer is far more reliable.

In order to estimate the percentage of the different varieties of leucocytes smears were made on glass slides, dried in the air, fixed and stained by means of Jenner's stain. In every case between 400 and 500 leucocytes were counted.

The original Arneth classification of the polynuclear neutrophiles was found to be too complicated and cumbersome to be of practical use, but to gain some idea of the possible changes that may have occurred to the nuclei of the polynuclear neutrophiles during the course of treatment with autogenous vaccine a count was made of the number of cells containing 1, 2, 3, 4, and more nuclei.

When I decided to report these blood counts in the form of a paper, I hoped to be able to give more positive statements than my later knowledge will permit.

In the last portion of my work I ran four so-called normal blood counts and three blood counts

FIG. 3.

FIG. 4.

where typhoid vaccine was given to presumably normal people. One of the so-called normal counts, a woman of 40, turned out apparently not to be normal at all. Her daily leucocytes ran 19,000, 16,000, 14,000, 13,000, and suddenly, after she had eaten a presumably normal plate of ice cream, that may have contained ptomaines, she ran a leucocyte count of 64,500, with a chill. Then it turned out that her menstrual period had been delayed eight weeks. This was discouraging from the "normal" point of view, and I stopped the blood counts, but I hope later on to make some more studies of this case.

With the other three normals the leucocytes had an interesting way of varying backward and forward between 17,000 and 5000. In fact, they did not seem normal at all.

The typhoid vaccine patients had sore throats or had colds from which they were either getting well or which they were just acquiring, so that as regards normal blood counts I am in the same quandary as the countryman who, when he saw a camel, called out: "There ain't no such animal."

However, in spite of such discouragements I still believe the systematic study of the blood, along the lines shown in these charts, are of distinct value in vaccine treatment.

In closing this report on the blood counts I wish to express my thanks to Dr. St. John for the perseverance and scientific accuracy which made these charts possible.

AUTOINOCULATION IN THE TREATMENT OF MOUTH INFECTIONS.

Autoinoculation consists of rubbing the infecting bacteria into tissues that have sufficient recuperative force to defend themselves by the formation of corresponding protective antibodies. A bacterial colony may have so overpowered the tissue on which it immediately rests that all power of antibody formation is destroyed. But if the mass of bacteria is mechanically removed and a portion rubbed into the healthier tissue adjacent, specific ferments are formed that not only will immunize the local part against further attack of such organisms, but the bacterial resistance of the entire body will be raised against these specific organisms by the distribution of their specific antibodies throughout the entire circulation.

This result, I believe, can be accomplished by thoroughly brushing and cleansing the teeth and gums.

No paper relating to mouth infection would possibly be complete without some reference to the ameba. The discovery of the ameba by Barrett and Smith may have a far-reaching effect on this disease. I have used emetin 1/3 of a grain administered hypodermically in the arm or back for ten successive days during the treatment, and have felt that as an adjunct it is a great help to the vaccine treatment for mouth infection. But I have also had remarkably good results where the vaccine was used without the emetin, results which for perma-

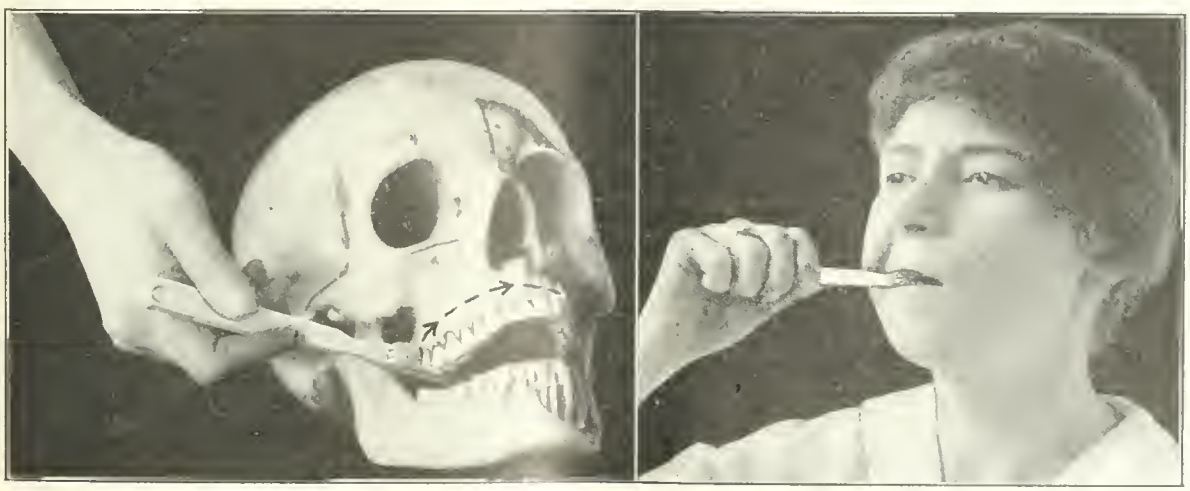

FIG. 5.

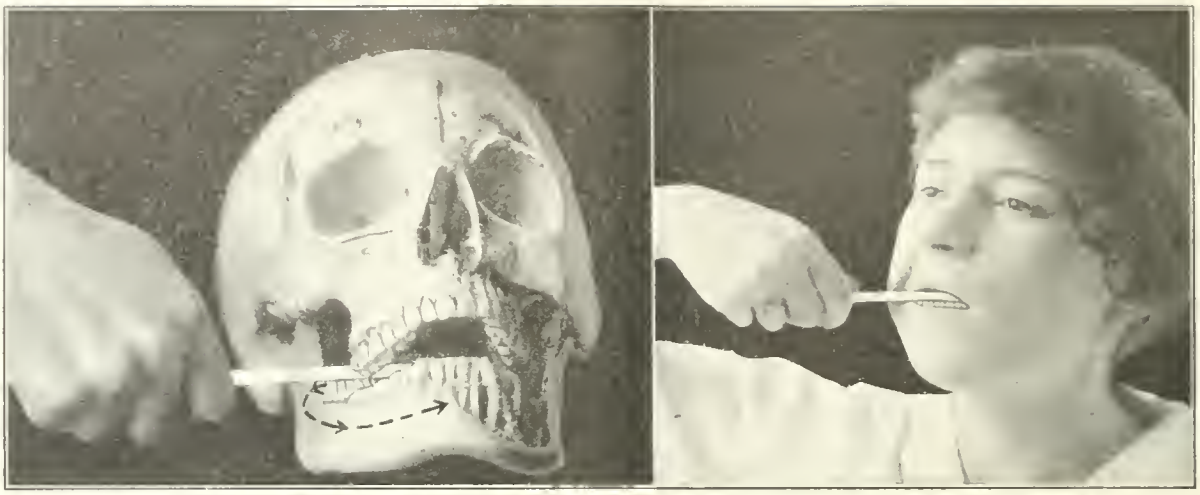

FIG. 6.

nency and rapidity of action were never obtained without the vaccine. I also believe that neither the vaccine nor emetine can cure a case of advanced mouth infection unless there is good dental surgery whereby the primary depots of infection are removed. And I believe that all cures so reported will be followed by a speedy relapse.

In my opinion, no single drug or vaccine can eliminate mouth infection when it is once intrenched. It can only be cured by the intelligent assistance of a practitioner who is able to discriminate just what surgical and therapeutic procedures will be effective, and any specific curative claim for surgery, vaccine or emetine alone will certainly retard, not advance, the cause of true oral hygiene. In this opinion Dr. Bass of New Orleans would seem to coincide when he says: "If a physician feels skeptical as to the specific beneficial effect of emetine, he can remove his skepticism by treating and observing a few patients. Both he and the patient are convinced of the efficacy of the treatment within a short time. After the endamebas have been destroyed by the emetine treatment, however, there are still left the lesions, which will require days, weeks, or months to heal." (*Journal of the American Medical Association*, Feb. 13, 1915.)

He then gives a beautiful description of the pathological lesions of this mouth infection, and goes on to say: "On account of the great prevalence of the disease and therefore the many sources of the parasite, such a patient with our present habits could hardly be expected to escape reinfection more than a few days, and certainly not as long a time as would be required for many of the lesions to heal. This would seem to take away the hope of complete cure."

Dr. Bass states that emetine or ipecac can only partly alleviate the symptoms, and therefore thinks there is no hope of complete cure of mouth infection. I agree with him as regards the efficacy of emetine alone, but I am not so pessimistic as regards the cure of mouth infection, as I am curing advanced cases as a yearly routine, where all the pockets of infection so beautifully described by Dr. Bass permanently disappear and where the rejuvenated gums reattach themselves to the roots and the loose teeth become free from pain and firm under the process of normal mastication.

But when we come to speak of real specifics for the cure of pyorrhea I should like to announce that I have one as effective for pyorrhea as the typhoid vaccine is for the prevention of typhoid fever. In fact, if pyorrhea has not advanced too far my specific will cure pyorrhea when it has actually begun.

My remedy is the autoinoculation caused by the scientific use of the floss silk and tooth brush. As

FIG. 7.

stated before, mechanical removal of bacterial masses is the first essential step in the elimination of mouth infection. Obvious as this is, I will venture to say that not one man in a hundred of this progressive company knows how to properly cleanse his mouth, especially the molars, so that they will be free from infecting masses, and yet this knowledge is of vital importance to the health of every patient. The physician has blindly accepted from the dentist palpably ineffective methods of tooth and gum cleansing. I only ask that some of the accurate technical observation usually employed in physical diagnosis generally be used in the elimination of bacterial masses from the mouth.

For instance, it is the common teaching and generally accepted theory that the tooth brush should be dentated and moved up and down the teeth so as to cleanse the interdental spaces. Now, the slightest observation will show that no tooth brush can really cleanse in between the teeth. The teaching of such an ineffective method prevents the true appreciation of the use of floss silk that really can be effective as a cleanser. The amount of space in the mouth available for free movement of the tooth brush is hardly ever more than two and a half inches, and yet the ordinary tooth brush is two inches long with bristles one-half inch long. With such an instrument bristle friction is practically impossible. The tooth brush should be smaller and the bristles shorter if the real bristle friction is to be obtained. It has been further claimed, and generally accepted, that the gums must not be brushed lest they will recede; while anyone who brushes and cleanses the gums will find that this is the sole way by which recession can be retarded and stopped. These errors are so obvious that it is almost unbelievable that scientific men ever accepted them for a minute.

Gum infection, or so-called pyorrhea alveolaris, starts usually between the ages of five and ten, and develops usually between the ages of thirty and fifty. As soon as the gum recedes from between the erupted teeth it leaves a triangular space. Unless this space is swept daily by floss silk, microbes will collect and remain in spite of the efforts of any tooth brush in Christendom until, having changed from saphrophytes to parasites, they penetrate the gums and peridental membranes, spreading diseases, wheresoever a weakened bacterial resistance most favorably permits. Yet no steps are being taken to effectively prevent this terrible evolution from occurring in our children's mouths. The efficacy of the scientific use of floss silk and a small tooth brush is capable of demonstration, and therefore, if the medical world will only demand that mouth cleansing methods must be effective the ineffective methods will disappear.

The test of any cleansing method is, does it cleanse? The method presently to be shown by me is not claimed to be the only effective method, or the most effective method possible. The method proposed is the only method I know of that will rid the teeth and gums of bacterial masses, leaving a film so thin that a mouth wash will have a chance effectively to come in contact with it. This will make it possible for a mouth wash to retard microbe growth until it is time for the next cleansing, and the mouth will thus be placed in a condition where its natural recuperative force will be able to combat the new inroads of the microbes. If such a method could be taught in the public schools it would increase the healthful years of our future citizens to an incalculable degree. I have taken the trouble to have such a method portrayed in motion pictures for educational purposes. If such instruction could be supplemented by the cooperation of a trained dental nurse in each class room, who would teach the children to effectively brush their teeth so that they could grow up strong and athletic, such teaching would be eagerly received. Every child likes to be dirty, the appeal for cleanliness alone would fall on deaf ears, but what would not healthy boys and girls endure to run, jump, or swim better? Such an appeal in their eyes would add a dignity to accurate tooth brushing that it now altogether lacks. To brush the teeth properly as much pain must be endured for the first ten days as is endured in the first days' training for a foot race. Brushing the gums and necks of the teeth during the first ten days makes them sore and inflamed, but if the brushing is vigorously and bravely continued each day, the gums become as hard and firm as the tissue around the finger nails. Therefore, if the child is informed of the value of this ordeal and encouraged to do this just as a trainer instructs and encourages the young athlete in the first painful exercises that will prepare his muscles for the boat race or the football field, the child will endure it cheerfully.

An effective method of mouth cleansing is as follows: The spaces between the teeth should be swept first with dental floss so that all bacterial masses will be removed from the sides of the teeth and the gums, as is shown in Fig. 1.

This will at first cause bleeding and make the interdental space sore. But if the infection has not penetrated beneath the gums beyond the reach of the floss silk, autoinoculation will soon cause a healing that is little less than miraculous. After using the floss silk the tooth brush should be used. As before stated, the tooth brush should not be over $1\frac{1}{2}$ in. in length and the bristles not over $\frac{1}{4}$ in. long. Fig. 2 shows the relative size of a tooth brush purchased in the open market compared with the size the tooth brush should be.

The bristles may be flat, as shown in the illustration, the principal thing to be avoided is too great bristle length, since bristle length by increasing the pivoting arc of each bristle, just so much reduces the bristle friction produced by the general movement of the brush, and it is bristle friction alone that cleanses the teeth and gums during the process of brushing. Bristles $\frac{1}{2}$ in. long will pivot $\frac{3}{8}$ in. each way without bristle friction. If, therefore, there is a 1-in. stroke the bristle friction stroke is only $\frac{1}{4}$ in., and if, as frequently happens, the tooth brush stroke is only $\frac{3}{4}$ in., there is no bristle friction stroke at all. My own observations have shown this to be a fact. The $\frac{1}{4}$-in. bristle under the same conditions would have a play each way of 3/16 in., which theoretically would cause only $\frac{3}{8}$ in. loss of bristle friction, but in reality it would be less, since the further the bristle extends from the back of the brush, the more readily it bends under pressure. As before stated, $2\frac{1}{2}$ inches is the average space for tooth brush motion found in the average mouth. Therefore, although there may be a $\frac{3}{8}$-inch loss in bristle friction, when the $1\frac{1}{2}$-inch brush is moved through a $2\frac{1}{2}$-inch space there will yet be a $\frac{5}{8}$-inch bristle friction stroke which is amply effective as a cleanser.

And so, having discussed the mechanics of general tooth brushing, let us proceed to inquire into the scientific method of tooth brushing as applied

to the human mouth. There are three motions: the rotary motion whereby all the gums and teeth anterior to the second molars are cleansed with vigorous whirling action; second, the drawing motion wherein the middle of the brush is placed behind the wisdom tooth drawn vigorously across the gum margins of the teeth. In each stroke care should be used to follow the inner curve of the arch with the entire face of the brush.

If at first the tooth brush bristles seem too stiff their excessive harshness can be reduced by placing the brush in hot water for a minute prior to using.

Let us now discuss motion No. 1 in its minute relations: The upper and lower front teeth should be placed edge on edge to avoid the lapping of the upper teeth and rubbed upward to the junction of the upper gum and lip, forward for a distance of a full inch or more, downward to the lower gums and lip margin, and then back to the original position. This should be done at least five or six times, as shown in Fig. 3.

The brush should then be placed between the cheek and the teeth on the right side. Here the same motion should be carried out. The brush should be rubbed upward to the junction of the cheek and gum, back to where the end of the brush is stopped by the overhanging curve of the lower jaw, then back to the start, when it is repeated five or six times as in Fig. 4.

This same motion should be repeated on the left side and the three movements of motion No. 1 are finished. After this movement has been thoroughly performed, if the second and third molars, upper and lower, are examined they will still be found to be covered with bacterial masses. And the reason for their undisturbed deposits is easily discovered. The curving side of the lower jaw lies so close to the upper teeth that no tooth brush can possibly get at them while the jaws are closed, and in the same way the two lower last teeth are excluded from the action of the brush by the fact that they lie behind and within the curving angle of the lower jaw. When the jaws are closed there is not $\frac{1}{8}$ in. room for tooth brush cleansing, but when the jaws are partly opened, the lower jaw swings back, leaving a space of a full ½ in. in which the tooth brush can thoroughly do its work, starting behind the third molars. Therefore, as just intimated, with motion No. 2 for the upper teeth, the mouth should be about half open and the lips and cheek held relaxed. The middle of the bristles of the 1½-in. brush should be placed at the back of the third upper molar and drawn briskly forward along the gum margin, care being taken to follow the curve of the gum with the entire face of the brush. (See Fig. 5.)

To place the brush back of the third molar the relaxed corner of the mouth should be pushed back by the back of the brush until the middle of the brush is directly back of the wisdom tooth. When this is done correctly the brush will be pointing directly at the wisdom tooth on the other side of the arch. The middle of the brush should be placed back of the third molar, not shoved in place by the point, as by shoving it the bristles will be so bent that the resulting pivoting of the bristles will cause the back of the upper third molar to get no bristle friction at all, and so the back of the third molars will not be cleansed.

Motion No. 2 in its action on the lower molar teeth is exactly the same as with the upper, except that instead of placing the bristles on the back of the lower third molar the bristles are directed downward on the gum back of the third tooth, and then with a sweeping, curving, downward sweep is brought sharply along the gum and cheek margins and the necks of the lower teeth. (See Fig. 6.) This motion should be done in the upper jaw and lower jaw, right and left, not less than five or six times each.

Motion No. 3 is comparatively simple. The middle of the brush is placed on the gum and tooth line behind the third molars and drawn sharply forward over the inside of the central incisors, care being taken to follow the curve of the arch with the entire face of the brush. The brush should be placed back of the last molars, not thrust back of them, as thrusting will cause a counter bending of the brush bristles and result in a pivoting that again will leave the back molars without bristle friction, and consequently dirty.

Motion No. 3 should be done five times on the upper and lower jaws, right and left, and when this has been properly done the teeth and gums will be free from bacterial masses, at least as free as the tooth brush can make them, and properly used, the tooth brush is one of the most effective instruments for cleansing the mouth. Improperly used, or used as it is ordinarily, tooth brushing is a delusion, but scientific, careful cleansing with implements of the proper size and shape will unquestionably add years of healthful existence to every man, woman, and child in the community at large.

1500 Locust Street.

PROVISION FOR WAR CRIPPLES IN GERMANY.

By DOUGLAS C. McMURTRIE,

NEW YORK.

EDITOR, AMERICAN JOURNAL OF CARE FOR CRIPPLES.

Coincident with the outbreak of the European war there was inaugurated in Germany an extensive system to provide, surgically and economically, for wounded soldiers crippled in action. During the past decade there had been built up a national organization dealing with the care of cripples—mostly children—in time of peace, and the first reliance was placed on the adaptation of existing agencies to meet the needs of adults in time of war.

Hostilities were declared on August 1, 1914 and on the 13th of the same month the Empress addressed to the president of the German Association for the Care of Cripples (Deutsche Vereinigung für Krüppelfürsorge) the following communication:

"Her Majesty, the Empress and Queen, expresses the wish that the activity of the German organizations for the care of cripples should not be hampered by the events of the war, but that they should, on the contrary, contribute their share toward the alleviation of present hardships. We should strive to prevent diminution in the scope of work by institutions for cripple-care, and must aid them to extend that work in certain directions. For instance, needy children, who are not at present being cared for, should be received into the institutions in order to relieve their mothers of undue burden.

"It also seems desirable that these institutions should undertake the orthopedic care of the wounded, as their entire equipment fits them for such work. Their facilities could also be utilized

to restore the wounded to their former industrial or professional status. . . ."

The association immediately issued to its members a questionnaire calling for statements as to the number of beds available for the war cripples, and details regarding the equipment and facilities of each institution. In an accompanying communication it was pointed out that each institution would have to meet the situation individually—some would have to crowd their children and discontinue classes, others might find an unoccupied building or barracks which could be used as an annex, still others might place some of their children in the care of neighbors or friends to make more room for soldiers; while, finally, in some cases benevolent friends might enable an institution to erect a special building which would remain useful after the close of the war.

The questionnaires were filled out and copies sent to the military and civil authorities.

The practical organization of measures for the care of war cripples fell to Dr. Konrad Biesalski, secretary of the German Association for the Care of Cripples. In order to establish the methods and principles of the work, Dr. Biesalski made a round of visits to the various institutions throughout the empire, a series of meetings being held at the different places visited. As a result, the following plan was evolved:

The scope of the work falls within two categories, [*a*] medical care (orthopedic and surgical treatment) and [*b*] social care (teaching of trades and securing employment).

As regards medical care, in order that the war-invalid may be enabled to resume work, the curative resources of surgical and mechanical orthopedics must be called upon, so that the maximum of physical recuperation may be achieved. Whenever possible, all fresh transports of wounded soldiers should first be concentrated in a large hospital which should serve as a central bureau for neighboring hospitals. Thence—granting adequate means of transportation—the soldiers, classified according to character of wounds or disabilities, should be transferred to other hospitals, particularly for treatment by specialists.

Experience has shown that a great variety of motor disorders and much subsequent treatment can be prevented if, during the healing of the wounds, the limbs are made to assume natural and reasonable attitudes and simple exercises are prescribed. Another important prophylactic measure is the high development of bandage-technique for purposes of transportation. The cases in the central hospital which will profit from treatment of an orthopedic character should be classified by an expert, and sent to suitable institutions.

When the orthopedic surgeon and specialist in the care of cripples from any district has been called to the front, his release and return must be obtained by the national association. This has been done in many instances. It cannot be questioned that the work of an orthopedic specialist at his civil post is of more value than his services in the field.

The cases for particular consideration are those of wounds which lead to serious motor obstructions through paralysis, the tearing of ligaments, stiffening of joints, and amputations. The best place for such patients is the institution for cripples which has at hand facilities to cope with the medical as well as with the social requirements of each case.

It was the unanimous opinion that these special institutions where soldiers would have to stay for extended periods should be preferably outside of large cities, in which latter it is practically impossible to preserve discipline. It was decided that in any case there should be an officer detailed as military director. It is imperative that the soldiers should not be sent to their families, as at home they would naturally neglect all physical exercise and, before long, become apathetic and useless. The military authorities must keep the men in an atmosphere of discipline for their own good. Towards the end of the treatment, the soldier may be given a leave of absence to return home for one or two weeks, but he remains a soldier, and as such must return to the hospital in order to be assigned to the work which has meanwhile been secured for him.

From this point on, there comes into prominence the second important feature of the work—social care. The cardinal requirement to success in this field is the education of the public to the idea that the cripple is not condemned to perpetual idleness, but that even a badly crippled individual may be taught to work and earn his living. This can best be accomplished by

(*a*) Continuous propaganda in the daily and technical press, to which end the efforts of writers should be directed in order that the question may be clarified from all possible viewpoints.

(*b*) Through lectures and visits to institutions for cripples. For illustrated lectures the lantern slides of the German Association for the Care of Cripples are available.

(*c*) Through advice to and persuasion of the wounded in hospitals, who, immediately upon their reception, should be made to understand that they will be enabled to continue their former occupations. Hospitals can be advised in this connection by the military authorities, and instructive literature can be supplied, as many hospitals are not acquainted with the technique of care for cripples. Medical organizations and the Red Cross can also be instrumental in this work of enlightenment.

(*d*) By an exhibit demonstrating the principles involved. Also by the preparation of an illustrated pamphlet for broadcast distribution. The workmen's organizations and insurance societies have stated that with the assistance of an illustrated essay of this kind their success would be assured, and they have undertaken to explain its contents to representatives of labor and to distribute it to employers and employees.

Public spirited employers will be glad to offer their former positions to old employees when they will return to them as cripples from the war. There will also doubtless be a deficit in the labor market after the cessation of hostilities. The largest employer, however, is the state itself, which must set a good example and provide work for those who have become cripples in its service. The railroads have long since adopted the practice of retaining the services of those injured in their employ, and the military organization has done the same. If each branch of the state machinery provides only for its own war-victims, thousands will be taken care of. The state can, however, go farther and, when placing orders with civil concerns impose the condition that a proportion of the laborers employed be war cripples. But all must first be taught that the cripple is able successfully to pursue an occupation.

The cardinal principle remains that the cripple must return to his old place, employment, and occupation, and thus be naturally assimilated by the community. Under no circumstances should the cripples be gathered in large colonies. The attempt has already been made to segregate them in colonies of from forty to fifty families, located near small cities, and provided with workshops. But this plan has been universally condemned as the colonies bear the stamp of the unusual. Occasionally it may prove advisable to place an individual cripple in an already existing colony, but in no case should this be done on a large scale. As soon as the conviction becomes general that the cripple can do work, the laborer, himself enlightened, will find no difficulty in resuming his former occupation. Employers will willingly allow for a period of partial incompetence pending adjustment to the new conditions of work.

It is important that the cripple continue in the same or in a closely related occupation, where his former experience will stand him in good stead. When it becomes imperative that the occupation be changed, the wisest course will be to find in the cripple's home town a teacher (manual laborer, shop manager, restaurant keeper, etc.) who would accept the invalid as an apprentice, possibly for a compensation to be paid by the military authorities or from private sources.

The establishment of separate workshops is inadvisable, according to the unanimous opinion of all counsellors; the method is expensive, open to the danger of "crowd suggestion," and would be hampered by lack of experience in the difficult art of teaching cripples—even more difficult with adults than with children. Furthermore, the 54 German institutions for cripples comprise 221 shops for industrial training, in which 51 male occupations are now being taught. In case of necessity these could be enlarged, and the required experience would there be available.

As to the method by which the appropriate work and position for the individual shall be ascertained, the cripple should first be transported to his home town, not to his family, but to an orthopedic institution in the district. By gradual exchange each institution will thus have an increasing number of cripples from its own locality. While the treatment is still progressing the organization for cripple-care connected with the hospital will find employment, in accordance with the wishes and capacities of the individual. This function should be the duty of a small committee consisting of an orthopedic specialist, a representative of the social care for cripples (minister, teacher, etc.), and a representative of the local labor organization.

In case the attempt to find employment through the city or district labor bureau fails, the next higher labor bureau will be advised, since the larger the section controlled by the bureau the greater is the chance for securing suitable employment.

There is in Germany to-day a network of labor bureaus distributed according to provinces and states and controlled from a central office. Wherever there are gaps the district administration will have to step in. Separate departments for partially incapacitated laborers exist in a few of these labor bureaus. Such departments will now be necessary and may perhaps become permanent. The establishment of special labor bureaus apart from the existing system is not advisable.

When the individual has secured employment the institution with which he was connected should keep track of him, so as to be in a position to assist him further if necessary.

As previously explained these principles were developed by the German Association and by Dr. Biesalski as a basis for the work. These methods are now being worked out by the individual organizations.

Beginning the middle of last December, there was held in the Reichstag, Berlin, a general exhibit dealing with the care of the wounded—the Ausstellung für Verwundeten und Krankenfürsorge—in which there was an important section dealing with provision for war cripples. There was exhibited orthopedic apparatus, and articles and pictures showing what badly crippled individuals can do. This exhibit was later sent to other cities. In connection with it there was held in Berlin on January 13, 1915, a great meeting to discuss "Kriegskrüppelfürsorge." Dr. Biesalski spoke on the principles of the work. Professor Schweining described the arrangements perfected by the army authorities. "The military authorities not only seek to heal but also aim to apply measures to avoid the unfavorable results of wounds; arrangements for this had already been provided in time of peace. In part special sections for orthopedic work were established or contracts were concluded with private institutions. A large number of orthopedists have been secured as consultants for numerous hospitals. For instance, in connection with the Garde-Korps, 24 medico-mechanical institutions are at the service of the military authorities. Also, arrangements have been completed with 107 health resorts for the after treatment of the wounded and sick. Artificial limbs and apparatus are procured and renewed by the military authorities. Special institutions have been established for the one-armed and the blind, and others will follow. Advisors with reference to trades are attached to the hospitals for those who no longer can follow their previous trades or think they cannot. Finally, he spoke of the special pensions, as the field allowance and the increase of pay for mutilation will remain as permanent compensation for those crippled in the war." Kirchner, the ministerial director, also spoke of the general co-operation requisite for success along this line.

An illustrated handbook dealing with the methods and principles of care for war cripples has been issued and is being distributed in large quantities. This booklet contains a directory listing 138 institutions or organizations concerned in work for cripples throughout the country.

It was estimated by Biesalski that the first few months of the war yielded 40,000 wounded whose motor affections were of so serious a character as to warrant their designation as war cripples. With the continuance of the war, and in view of the fact that with each man are involved several members of his family, it is conservative to say that the interests of hundreds of thousands are at stake in the work.

Organizations and individuals have entered enthusiastically on their tasks. The Kriegskrüppelfürsorge has now reached such proportions that Dr. Biesalski, having given the movement its impetus, has turned over its further organization to the military authorities. In this way the permanence of the work and its uniformity throughout Germany is secured.

It is interesting to note that in the first 800 wounded soldiers under Dr. Biesalski's care, it was found that with but few exceptions—less than 4 per cent—all could continue their former employments.

The care of war cripples is being worked out in various cities. The plan in Frieburg has been described by Dr. Burkhardt. A central organization has been established under the authority of Dr. Rosin. There are three sections. The first, the economic section, is composed of experts on various trades and on labor conditions. On this committee have been appointed two professors of social science, and a practical jurist. Their duty is to advise the individual as to the choice of a suitable employment. The second, the educational section, is composed of the presidents of the trades, commerce, and agricultural schools. They are empowered to appoint to teaching positions. The third, the clerical section, is under a competent director.

The practical results of this system are shown in the following cases:

(*a*) Paperhanger, 24 years. Amputation of left leg. Has good artistic ability and has been placed in trade school, where he is being trained as a decorative artist. His former employer has agreed to re-engage him.

(*b*) Baker. Left foot crushed. Is being instructed in bookkeeping and commercial arithmetic. Will enter grain dealing trade and manage bakery of a deceased relative.

(*c*) Farmer, 23 years. Loss of right arm. Is being trained in agricultural science and in writing with his left hand. Will take charge of the business end of the agricultural interests of his brother's farm.

The work is slow and final results will not be forthcoming for a considerable time. But the manner in which the problem is being met is unquestionably sound.

SOME SUGGESTIONS CONCERNING THE TREATMENT OF THE GASTROINTESTINAL SYMPTOMS OF PELLAGRA.

By GEORGE M. NILES, M.D.,

ATLANTA, GA.

In this brief article the writer will not discuss the general treatment of pellagra, with its varied and manifold phases, but will endeavor to advance some helpful suggestions regarding the management of the gastrointestinal manifestations, and offer some concrete prescriptions that have seemed of material benefit.

It should be admitted that the disturbances of the digestive tract result from irritation of the central nervous system, plus elimination of toxins through the gastrointestinal mucosa. Let this point also be stressed—many of the apparently acute symptoms, such as vomiting and diarrhea, are not due primarily to local irritation, but are referred from the nerve centers. Based on these postulates, therefore, the following is offered:

Beginning with the inflamed mouth, tongue and lips, these accessible surfaces should receive a daily application of a silver nitrate solution, twenty grains to the ounce. The patient should be supplied with an abundance of a 10 per cent solution of the alkaline antiseptic liquor (N. F.), and admonished to wash his mouth frequently with it, allowing some to trickle down his esophagus each time. Should the lips be raw and cracked, they can be softened and protected by applications of white vaseline.

Nausea is generally controlled by three-drop doses of spirit of bitter almond, given as often as needed. The following will be found efficacious in many cases:

℞ Spts. amygdalæ amaræ, ℥ ii.
Resorcinolis, gr. x v.
Lactis bismuthi, ʒ ii.
Aquæ, qs. ad. ℥ iv.

M. Sig.: One teaspoonful every half hour when nauseated.

As a simple carminative and aid to digestion in hyperacid cases this is worth while:

℞ Spts. lavandulæ co., ℥ ii.
Resorcinolis, gr. x v.
Mist. rhei et sodæ, qs. ad. ℥ iv.

M. Sig.: One teaspoonful after meals, and repeat as needed for fulness or distress.

In hypoacid or achylic conditions, such as are found in late cases, this will prove acceptable:

℞ Tr. nucis vom., ♏ ii.
Acid. phosphoric. dil., ♏ iv.
Elixir calisayæ co., qs. ad. ♃ iv.
M. Sig.: One teaspoonful after meals, in water.

For the burning stomach, one of the neuroses often and bitterly complained of, this prescription is generally of service:

℞ Chloralis, ♏ ss.
Strontii bromidi, ♏ iii.
Aquæ chloroformi, qs. ad. ♃ iv.
M. Sig.: One teaspoonful in water every three hours.

Gastric lavage is seldom indicated, though occasionally, in the presence of an excess of sticky mucus which constantly arises from the stomach, this procedure may be employed.

The writer recommends for the lavage an aqueous solution of potassium permanganate, 1 to 10.000, or ichthyol, 1 to 2.000.

Many pellagrins are either without appetite, or develop a marked sitophobia, or fear of food. Under such conditions much tact is needed, lest a dangerous malnutrition supervene. The following stomachic, however, has seemed quite helpful in many such instances:

℞ Tr. condurango, ♏ iv.
Tr. nucis vom., ♏ ii.
Tr. gentianæ co., qs. ad. ♃ iv.
M. Sig.: One teaspoonful in water before meals.

The occasional constipation is best managed by small doses of castor oil, or liberal doses of liquid paraffin, or gentle enemas. Drastic cathartics are inadmissible—in fact, any of the cathartic drugs should be administered with caution, if at all. The constipation can so easily merge into an obstinate diarrhea, that only the mildest means for emptying the intestinal tract should be employed.

The diarrhea of pellagra is generally compensatory, and to an extent salutary, except in terminal stages, or where actual and deep-seated local irritation is present. Bowel movements not exceeding two or three daily should not be checked. When the diarrhea is excessive, ten or fifteen-grain doses of tannigen, given five or six times daily, have usually sufficed. In rare instances one-grain doses of opium may be given, but opiates should be avoided if possible.

This prescription is also recommended as an astringent:

℞ Tr. kino.
Tr. catechu, aa ♏ iv.
Lac-bismuthi, ♃ i.
M. Sig.: One teaspoonful after each loose action.

In states of intractable diarrhea, pure kerosene oil may be injected into the rectum and colon. A pint may be introduced at gentle pressure from a fountain syringe, and allowed to remain in the bowel for half an hour. The oil does not seem to be absorbed, and in one instance, where, through a misunderstanding of orders, the oil was allowed to remain in the colon for over three hours, no ill effects were noted. These injections may be administered three or four times, on alternate days.

The diet in pellagra should be as liberal as practicable, always insisting on the daily ingestion of the flesh proteins and either dried beans or peas. Fresh meat and the legumes seem to fill a specific requirement, and may be eaten at any stage of the disease. An abundance of the other nutritious foods should also be allowed.

While the woody vegetables, or those containing much cellulose, are ill borne in diarrheal conditions, they may be allowed when the patient is constipated.

Until the zeist theory is disproved absolutely, the patient should be given the benefit of the doubt, and all corn products should be prohibited.

It is a mistake to limit the diet on account of diarrhea, unless it is plainly of an irritative type, or appears as a terminal symptom. Pellagra is an exhausting malady, and the pellagrin who is well fed, regardless of digestive disturbances, except the most acute, has a vastly better outlook for recovery than one who is dieted in strictly orthodox fashion.

The foregoing suggestions are based upon the observation and treatment of eight hundred cases of pellagra.

DELIRIUM.*

By EDWARD LIVINGSTON HUNT, M.D.,
NEW YORK.
ASSISTANT PROFESSOR OF CLINICAL NEUROLOGY, COLL. OF P. & S., COLUMBIA UNIVERSITY.

THE best definition of delirium is that given by Tuke. He describes it as a "perversion of the mental processes, the perversion being manifested in speech or action." Delirium is characterized by incoherent speech, hallucinations, delusions, illusions, restlessness, watchfulness, apparently purposeless actions, and inability to fix the attention. Its presence, therefore, implies the existence of a general disorder of the mind. It should not be used synonymously with the term insanity.

Delirium is one of the first and most frequent conditions which the general practitioner is called upon to diagnose and treat. The child has some slight disturbance. There is a rapid heart action, and a high temperature. Then follow confusion and restlessness. The patient struggles, cries out, and plainly indicates that he sees strange objects and hears unusual sounds, in other words, that he has both delusions and hallucinations. His mental faculties are disturbed, unduly aroused, and perverted. He is delirious. The condition from which he is suffering is simple delirium. These symptoms, which complete the picture of simple delirium, represent the fundamentals of every type of delirium. There are variations and the variations which enable us to separate deliria into different classes result from the several factors which cause the particular delirium in question.

Delirium may be severe or mild, but in either type it is a condition of short duration. It usually lasts a few days and rarely more than two weeks. It may vary in intensity from the mildest type known as "flightiness" to the most severe—an intense maniacal condition.

It accompanies many forms of infection as typhoid, scarlet fever, malaria, etc.; it may be the result of exhaustion, as in numerous instances of the collapse or exhaustion delirium, following lactation and wasting disease; it may be directly produced by drugs, either self-administered, as the alcoholic delirium, or administered by the physician, as evidenced in the bromide intoxications; it may be due to poisons formed in the body, as in anemia or gout; it may be post-operative; it may be traumatic; it may be due to some source of irritation, as a clot or neoplasm in the cerebrum; or to some interference of the cerebral circulation, as illustrated in the

*Read before the East New York Medical Society, March 18, 1915.

delirium of arteriosclerosis and senile dementia. It may be psychogenic in origin, as is the delirium in dementia precox or hysteria.

The best classification of delirium is the one proposed by Dercum of Philadelphia. He divides all deliria into two classes: (*a*) The Febrile Delirium, (*b*) The Afebrile Delirium. *Febrile deliria* are those which accompany the various acute infections, the exanthemata and the various acute visceral diseases, such as pneumonia. The afebrile deliria are those which are met with as sequelæ of various infectious diseases, as a result of various intoxications, and after trauma or shock. According to this classification you will see that a patient may suffer from a febrile delirium during the period of his illness, and an afebrile delirium during the period of his convalescence.

The febrile delirium is one which is always accompanied by the physical signs of the particular disease from which the patient is suffering and the temperature. It is the result of the action of certain toxins upon the cortical neurones. It is the delirium which we meet in typhoid and pneumonia, in rheumatism, and scarlet fever, etc. It may vary greatly in severity. Thus a patient of defective ancestry, endowed with a highly nervous temperament, is much more apt to develop a delirium than a phlegmatic individual. Again, it may vary according to the intensity of the toxins. The patient may simply wander a little, may become noisy and violent or he may abound in delusions. Therefore the two factors which influence the febrile delirium are the intensity of the toxin and the degree of resistance on the part of the individual. Its characteristics are those of simple delirium—delusions, hallucinations, illusions, restlessness and insomnia, etc., etc. It varies somewhat in the different diseases.

The mental symptoms arising from the toxins of the different infectious diseases do not vary, however, to so great an extent as to warrant a differentiation. There are, however, a few minor differences which I shall point out. In *malaria* the delirium is sudden and intermittent. It may accompany or replace the fever. It is rarely present in the quartan variety—occurring with greatest frequency in the tertian and quotidian.

In *typhoid* Aschaffenberg distinguishes two types, the first in which there is no pseudo-motor activity, but many hallucinations and delusions of a persecutory and threatening nature; the second—which may develop from the first—shows great psychomotor activity a rapid development, with marked hallucinations and delusions. There is a considerable flight of ideas and confusion of thought, together with an anxious and emotional state.

In *hydrophobia* the hallucinations predominate; periods of quiet occur.

In *acute chorea* the delirium is one characterized by a clouding of consciousness, with a peculiar dreamy confusion of thought. The patient displays anxiety, marked irritability and outbursts of passion. The speech is disjointed. These patients suffering from chorea have delusions, but they are neither very clear nor very elaborate.

The afebrile delirium is far more interesting than the febrile. It, too, is an affection of short duration, generally never extending beyond a few days. It may occur in many and widely different conditions. Thus, it may be the delirium which is the result of febrile conditions, the delirium which follows surgical shock, great fright, sudden loss of blood, and toxic conditions.

There are two factors important in its production: (1) Exhaustion, and (2) Toxemia.

The afebrile delirium presents both physical and mental symptoms. It can best be described by relating the symptoms of the exhaustion or collapse form of delirium, which is simply another name for the afebrile delirium. This is fairly common. It may be due to inanition, to excessive lactation, or to a wasting disease. It may follow a great loss of blood, as a post partum case, or chronic nervous exhaustion.

It is characterized by an acute onset. There is usually a loss of appetite, a few nights of insomnia and restlessness. Immediately there appears a period of motor excitement with great incoherence of thought, and marked clouding of consciousness, accompanied by both delusions and hallucinations. The patient becomes greatly frightened. The attendants and friends startle him as they come near.

The figures on the wall paper assume fantastic shapes; every sound is perverted and new ones are heard. He is absorbed in his own fancies. Music is heard, and crowds fill the room. The patient is terrified, and either cries out loudly or assumes a crouching attitude in one corner of the bed. I can remember one patient who dreaded the approach of darkness, as he told me that every night the night nurse attempted to cut off his arms and legs. He thoroughly believed this, and whenever the night nurse approached to feed him he would grapple with him and fight him off as if in reality his life were at stake. He subsequently told me that his suffering every night was the greatest that you could conceive of. Physically these patients show a great loss of flesh, a pale and clammy skin, a subnormal temperature and a pulse that is weak and irregular. They eat very little and sleep very little.

Some of the patients either cry out loudly or talk in a whisper, assuming a confidential mood. I can recall another patient suffering from an exhaustion delirium who was too weak to get out of bed but whose hands were nevertheless in constant motion. He would draw me down to the level of the bed and then in a startled manner whisper that he was being pursued by a black man; at another time that the room was full of black squirrels.

These patients are generally worse at night. At the present moment I have under my observation a lady who is recovering from an attack of exhaustion delirium. She believes that thieves come every night and strip the apartment. The fact that the furniture is still there makes but little impression. Only a few days ago when I asked her if the thieves had come last night, she replied no, but that they were coming to-night and that she must find a place to sleep, as to-night they would even take her bed.

The delirium from exhaustion is characterized by great motor activity, incoherence of thought, and involvement of apprehension.

The duration of this psychosis is brief—two or three weeks. The onset is sudden and the return to consciousness is sudden. Following a sound sleep these patients may wake in a refreshed and normal state of mind. The prognosis in these cases is good, provided always that the exhaustion has not gone too far and that the condition is recognized early enough to permit of the proper treatment.

Another instance of the afebrile delirium is the delirium produced by drugs. It occurs with great frequency and is most apt to follow the injection of bromides—but may result from hyoscine, chloral, veronal, morphine, antifebrin, etc. The action of

the poison is probably not the only factor in its causation. Insufficient food, loss of sleep, digestive disturbances and general exhaustion all act as contributing causes. The drug or alcoholic deliria are fundamentally the same, differing only in special characteristics. The physical signs are coated tongue, foul breath, pasty complexion, and defect of speech. There is an unsteadiness of the gait, and slight tremors. The reflexes may be slightly active, and the temperature may be above the normal. The mental symptoms are dullness and hebetude, with a tendency to dip down to a lower level of consciousness. Hallucinations are present; the faculty for both recent and old events is good.

This form of delirium is more than any other dependent upon the degree of resistance of the patient as one patient may take with impunity a dose which in another will precipitate a severe delirium.

Several years ago I saw a most interesting case of drug delirium. A man of fifty, whose business it was to make umbrellas, had been taking chloral for the past eight years. He told me that at the end he was taking 150 grains a day. He then stopped the chloral and began taking veronal. In time he stopped this and returned to the chloral, and began to drink heavily.

He became very irritable, squandered his money and forgot what he did with it. He would open his place of business early in the morning and then lock the door, shutting out his customers. He became very suspicious, and had marked hallucinations. He then developed delusions of grandeur and believed that he possessed great will-power. He would make mistakes in his checks, and in writing would leave out words. He became then greatly depressed.

The physical examination showed a man, bloated and anemic, weeping, and suffering from great mental depression. He was very slow in all of his movements. The pupils were equal and reacted to both light and accommodation. The tongue was coated with a brown fur. His gait was ataxic; movements of the upper extremities very uncertain; the knee-jerks were present under reenforcement. He had delusions of grandeur. There was an optic neuritis in his left eye. The diagnosis that he came in with was general paresis. We stopped his drugs and in three months he was perfectly well.

The afebrile delirium must be distinguished from the delirium occurring in epilepsy, hysteria and alcohol. It would take too much time to go into details and describe each one of these separately. I will simply mention the delirium occurring in Korsakoff's psychosis, because that is the most common and apparently the least understood.

Korsakoff's disease is a polyneuritic psychosis. In other words, it is a neuritis with mental symptoms. It may, however, manifest itself without neuritic symptoms. The aetiology in the large majority of cases is alcohol. There are other conditions which may result in Korsakoff's disease, and of these the most common are typhoid fever, pyaemia, jaundice and tuberculosis.

The cardinal symptoms of Korsakoff's psychosis are disturbances of memory and pseudo-reminiscences. These patients are disoriented, they do not know the date, the season, or the time of day. They are unable to remember what they ate for breakfast and cannot say whom they saw last night or when they received a visit from a member of their family. They are, however, never at a loss to supply answers to your questions and always have ready a story, highly improbable and yet prolix to a degree. I have one patient in my service at the City Hospital who is so feeble that it is with difficulty that he is able to leave the ward. Three months before his admission he was quite himself, was present at his daughter's wedding, and was able to take care of his family. When I last saw him he was so feeble that he could scarcely get about the ward, and rarely went out. Yet when I questioned him as to what he had done yesterday he at once told me a long and elaborate story about his having taken a long walk down Broadway. A few moments later to the same question he replied that he had spent the morning fishing. Not satisfied with this reply, he then went into great detail, telling me the character of the expedition, the kind of bait used, and even specifying the number and kinds of fish caught. His memory was very defective; he could not tell the time of day, or remember when his family had last been to see him. Usually he would say that his daughter had just left him, or that the whole family had all been to see him the day previous, whereas no one had called for a week. The retention of ideas and memories in this psychosis is markedly altered.

This patient gave an alcoholic history, covering a long period of time. The physical signs were those of lost knee-jerks, and paralysis of the anterior tibial muscles.

The treatment of delirium comprises four distinct factors: (1) To secure sleep, (2) To overcome the motor unrest, (3) To prop and maintain the patient's vitality, (4) To discover and if possible remove the cause.

To secure sleep: In endeavoring to secure sleep you should always bear in mind that in a delirious patient the effect of a drug may be the very opposite to that which you intend. If he is suffering from an exhaustion or toxic delirium, drugs will aggravate. Therefore, if possible, avoid drugs. Resort to hydrotherapy. The hot bath, given at a temperature of 90-95 per cent. is one of the best methods at our disposal. Patients can be placed in the tub, and kept there for periods varying from one-half to one or two hours. The water should be allowed to run continuously, and a bath thermometer kept in the tub, so that a steady and regular degree of temperature can be maintained. If this is not practicable, the best substitute is the wet pack. This consists of a sheet wrung out in warm water, which covers the patient. Over this are placed blankets tightly drawn, with the arms held down. The patient should be kept in this for an hour. If drugs must be used, the least harmful are trional, veronal and medinal. Paraldehyde is excellent; it produces rapid results.

A most important item in the treatment of deliria is the conservation of the strength of the patient. A delirious patient therefore should be at once put to bed, and kept there. Liquid nourishment is of great value, and should be given constantly and persistently. The best form in which to administer it is that of egg and milk.

Close attention should be paid to the heart action. If there is any indication of cardiac or circulatory failure, immediate resort should be had to strychnia and digitalis. The former can best be given hypodermically. Elimination on the part of both bowel and kidney should be carefully attended to. In a word, then, the keynote of the treatment of deliria is rest, hydrotherapy, liquid food, elimination, and stimulation.

41 East Sixty-third Street.

FULGURATION IN GONORRHEAL FOLLICULITIS.*

By GEORGE KNOWLES SWINBURNE, M.D.,

NEW YORK.

We constantly read in current literature that the treatment of gonorrhea is unsatisfactory, and the fact that there is a multiplicity of drugs recommended, and more are being sought after, is proof that the treatment is unsatisfactory. I have felt for many years that there was no acute, infectious disease the treatment of which was so satisfactory as it is in the case of acute gonorrhea if begun within the first few hours. And it is perfectly possible for every one to get such treatment in the first few hours if they can be made to realize the importance of time as an element of treatment. In the paper that I read in 1908 before the American Urological Association on "The New Silver Salts, Their Advantages and Limitations," I made the statement that, with any of the new silver preparations where the silver is combined with albumin in some form, if the disease were seen within the first twenty-four hours of the outbreak, in the vast majority of cases it could be throttled, that is, it could be kept from advancing any deeper into the canal, and also from penetrating any further into the tissues. And I stated that this was as true in primary cases as in those who had had multiple attacks. Now, the limitation of these silver salts is that, while the disease can be throttled and can be kept from going any deeper if rightly managed, the disease shows a proneness to relapse if treatment is intermitted; nevertheless the injections of these silver salts can be kept up indefinitely without any harm to the mucous membrane. But there are other means which can be employed after the case has reached the point, while under treatment, in which nothing but epithelial cells can be found, except possibly a few pus cells here and there, and absolutely no gonococci. We know that in a large proportion of these cases if the disease is allowed to go without treatment for forty-eight hours, or possibly three days, or at the outside four days, there will be a relapse, and the reason is that one or more follicles within a short distance of the meatus are infected. The medicine does not reach into the depths of that follicle, and that is the sole reason that the case is not cured at that time. I have often tried to search out these follicles by the use of the meatoscope, or urethroscope, but generally with ill success unless the infected follicles were very close to the meatus. I have also tried other means. Now some of these primary cases can be kept at the point where there is no inflammation, by daily injections, or by injections used every other day on the part of the patient, or even perhaps twice a week, and in these cases there will be no appearance of the disease. And yet if they neglect the use of this treatment a relapse will occur. I have known such cases to last as long as six months, and even longer, and I have tried various means to bring them to a quicker close.

One method that I have used has been successful in some cases, that is by daily hot irrigations of one of these silver salts, starting at a temperature of 115°-120° Fahrenheit, and gradually increasing up to 130°-135° for a period of three weeks or so, after which there will be a complete disappearance of the tendency to relapse, and evidently a cure of the case. Some of these cases, however, have relapsed just the same at the end of such a time.

By the way, in passing, I wish to say that now for a long time I have ceased using hot irrigations in the acute stages until the case has reached this point of showing no pus or gonococci, but only epithelial cells, for I have become convinced that in my own hands in some cases, there is a marked tendency for the disease to be carried deeper into the canal by their use.

Now, the first case in which I attempted fulguration was that of a physician who came to me after having attempted to treat himself for four months by using anterior injections of argyrol. During that time he found he had the very condition which I have described above. No posterior urethritis had developed during that time, but if he let up at all he would relapse. I first suggested the daily irrigations of hot solutions. At the end of the week nothing but epithelial cells could be seen, no gonococci, although the day that he came there was a marked purulent discharge containing numerous gonococci. But in view of the length of time that he had his trouble, I did not stop at this point, but kept up the daily irrigations for two weeks longer before allowing him to intermit treatment for even a day. Then I let him go without treatment only forty-eight hours, when there was a marked return of the symptoms so that now he was exactly as he was the day he came. We went back to our hot irrigations. Then when I had again got the condition down to a showing of nothing but epithelial cells, I injected the urethral canal with the silver salt and had him hold it in for ten minutes. I then put him on the operating table and examined his urethral canal with the Buerger urethroscope, carrying the window as far down the canal as possible without running the point of the instrument into the posterior urethra at all. The reason for using the preliminary injection was to prevent the possibility of carrying infectious material down the canal from the infected follicles. In this case I examined the anterior four inches of the urethral canal, the entire internal surface—the floor, side and roof. Curiously enough, in this case, I found no follicles on the floor of the canal, but I found in the roof six or eight wide-mouthed follicles, with congested rim, beginning at about three and one-half inches and running forward at short distances apart. At that first sitting I had my wire ready and was able to fulgurate each one of those follicles. Then I let him go for a week, having him use his ordinary injection at home once a day during that week, and on the second examination I found that a change had taken place in several of these follicles. Although they seemed to be wider open they had lost the inflammatory edges; some of them were wider open than they were before, but there was no pus coming from them. Nevertheless, I fulgurated each one again and repeated this a week later. Then I let the patient go for a week without using any injections at home, telling him to report if he noticed a relapse. That seemed to end the condition altogether; there were no relapses and he continued well after that.

Since then I have done this fulguration at an earlier stage in a large number of cases where they have shown this tendency to relapse. In the majority of these cases I have found that infected follicles occur more frequently in the roof of the canal, and very seldom have I found any on the floor, though I have in some cases. There were some

*Read before the American Association Genito-Urinary Surgeons, White Sulphur Springs, May 18, 1915.

cases showing this tendency to relapse in which I could not find any follicles anywhere. I have examined such cases more than once, and after explaining to the patient the probable reason for his constant relapse, and the importance of treating himself by keeping up the daily injections, these cases have ceased relapsing in a shorter time than have those in which I found infected follicles.

I have found this method of fulguration to be of great value in those chronic cases of folliculitis in which we find a beaded condition of the urethral canal. After fulguration, this beaded condition disappears, and the cases clear up very satisfactorily.

Now, in doing this fulguration I happened to possess the older style of the Buerger urethroscope, and my method was to bare the fulguration wire for one-quarter to three-eighths of an inch of its point, bending the wire at an obtuse angle at the point so that with the instrument in position, in pushing forward the wire, it comes into view and will readily touch the mucous membrane; then all that I had to do was to see at about what point the wire would hit the mucous membrane, place the window of the instrument so that when the wire was advanced the point would enter the follicle. It was not quite so easy to do this as it is to catheterize a ureter, but by a little patience I got so that I could do it quite as readily, and now with the latest Buerger which has a small lever with which one can guide the wire more readily, it is perfectly feasible to do it in the manner that I have described.

During the examination and during the treatment I always have an irrigator attached to the instrument, so that there is a constant stream of cold sterile water running, and in turning on the electric current I simply leave it on for a second or so. If the water is not running the sensation of burning is a little greater than when it is running. Patients very quickly get used to it and do not mind it, though some make a good deal of fuss. I always begin at the deepest follicle that I can find, and work my way forward. In some cases there are only two follicles, and in some, as I have reported, there have been as many as eight. At each follicle I turn on the electric current two or three times, doing it for one or two seconds each time, according to the way the patient acts. I have made the examinations and treatment once a week; in the acute cases the patient uses his injection of silver once or twice daily at home during the interval. I do not recall having made more than three applications of the fulguration in any one case, *i.e.* in the acute cases. In some chronic cases I have made, I think, even four, perhaps more. This method has proven quite satisfactory in my hands.

FETID BRONCHITIS.

By BEVERLEY ROBINSON, M.D.,

NEW YORK.

One occasionally meets with a case of bronchitis in which the sputum and breath are foul. The bronchial attack may be acute and the fetid smell may last only a short time. Usually, where the discharge from the bronchi is specially offensive, the case has already become somewhat chronic.

If the putrid condition remains for a while and resists usual medication general and local, the disease is both rare and obstinate. When it attains unusual severity, it comes on by degrees and usually continuously. It is usually occasioned by a previous attack of influenza, or by an unresolved pneumonia.

It may be, of course, connected with pulmonary tuberculosis, in which there is already cavity formation, or a limited empyema, which has found exit through a bronchial tube. In the great majority of instances, where we have fetid bronchitis which truly deserves the name, by reason of the quantity and character of the sputum, there is present more or less dilatation of the bronchi. This dilatation may be localized or general. It may affect only a limited area of one lung; it may be recognized as being in one, or both lungs, in a wide extent. When it is extensive it is apt to involve the lower lobes of the lungs; either, or both. In these instances, the larger bronchi are often much distended, and in a somewhat irregular way.

When the dilatations are localized they are apt to be in saccular shape and form more or less large and numerous cavities. One or more of these cavities may be near the surface of the lung at the apex, or base, and frequently the pulmonary and costal pleura adjacent to the large sized cavity are very adherent. At least, this is true when the disease has lasted several months or years.

The mucous membrane of the bronchi, where the disease is diffuse is red, congested, thickened, irregular. The elastic fibers and muscular tissue are often atrophied. There may be ulceration—communicating with lung tissue and causing limited destruction and maybe gangrene. The vessels are thin and dilated, hence not infrequently spitting of blood or considerable hemorrhage. Where the cavities are saccular they are often surrounded by fibrous tissue, which has contracted and dilated the bronchi in this way. The fibrous tissue is the result of a previous pneumonia and may be connected with pleuritic adhesions, which have sent projections into the lung.

The essential symptoms of fetid bronchitis are the large amount of putrid, purulent sputum and the nauseous, most offensive breath. The two together are of such a nature occasionally that the patient is practically ostracized and becomes unbearable to others. As a rule, the condition is without fever and the patient may only now and then have an acute exacerbation. The cough is paroxysmal and comes on in the morning and at night, when the patient expels a large amount of fetid sputum. The cause of the cough and expectoration is either because the bronchi are distended with more sputum than they can carry without rejection, or else the sputum has reached a position in the bronchus which is relatively healthy and cannot bear irritation from foul secretions.

The sputum usually is coughed up without much difficulty. The quantity is often very large, as much as one or more ounces at a time. The immediate cause of the fetid sputum and breath is the presence of different microorganisms, which have occasioned decomposition of the bronchial secretions. Among these Pfeiffer's bacillus and the pneumococcus are most frequent and productive. They may be mingled with many others. The sputum when it stand for a while separates in two, or even three, layers. The lower stratum is mainly pus and granular detritus. The intermediate layer, a turbid liquid, composed of mucus and pus and the upper layer is mucus and frothy. If the lung be tuberculous, either we may find tubercle bacilli under the microscope, or shreds of pulmonary tissue, where a cavity exists.

Frequently, the diagnosis of bronchial dilatation is very difficult to make positively, partly by reason of symptoms referable to affections which have preceded and caused it. There is little doubt that not a few cases of arrested pulmonary tuberculosis are none other than instances of bronchiectasis.

The presence of tubercle bacilli in the sputum is the one sure way to distinguish between them. The symptoms of the two diseases may closely resemble one another. This is especially true if there be fever, notable loss of flesh and strength, and continued cough with abundant purulent expectoration. The outlook in these cases, even of moderate severity, and especially if they have lasted several months already, is none of the best. They do not die—but they continue in about the same condition, neither better nor worse for a long while. Of course, they are liable as those affected with other diseases, to acute complications more or less grave. An accession of cold in the form of a fresh attack of bronchitis will aggravate the subacute, or chronic, condition—but will not terminate fatally. Such is not true of intercurrent broncho or lobar pneumonia, or empyema. These complications not infrequently bring on death more or less rapidly. In most cases of fetid bronchitis the general health has shown impairment for several years and the patient has also been a victim of privations, unsanitary surroundings. Behind them is a poor constitution with a hereditary history none of the best.

As to treatment, what may we do? The best air, the most nutritious food, freedom from exhausting work, are all indicated. A specially dry climate with rare atmospheric changes of any degree coming on suddenly should be recommended. Such is found in some parts of California and upper Egypt in the winter. In the summer, portions of the Adirondacks and Sullivan County, N. Y., are desirable locations.

Internally, an ordinary tonic treatment with the hypophosphites of lime and soda is about as useful as anything I know in that line. Of all drugs none is so useful locally as beech wood creosote properly administered. Internally, the dose must be small; not more than one half minim, given every two or three hours, with a little glycerin and whiskey. Locally, the use of beechwood creosote with the perforated zinc inhaler is the best means to correct fetor of the breath and sputum and to modify the diseased bronchial membrane. The inhaler must be worn many hours in the day to be of real utility. The ability to do this comes to many only after the lapse of a few days, or weeks. A formula I have long used is probably quite as good, if not better than others. It is equal parts of beechwood creosote, alcohol, and spirit of chloroform. Of this from ten to twenty drops must be poured on the sponge of the inhaler, and repeated as required.

The use of creosote in concentrated vapors in a tightly closed room, evaporated from an open dish or vessel, I do not approve of. It is too irritating to the eyes and nasal passages and I believe would, if persisted in, probably affect the kidneys undesirably. This method was strongly commended many years ago by Chaplin and is described in text books and special articles on bronchiectasis.

Mendel's system of intratracheal injections do not convince me as to their real utility, and I must consider the distress occasioned by them overbalances any possible desrable results, which at best, must be temporary.

Ephraim's and Guisez's methods of injecting drugs, referred to by Meyer, do not impress me better than the use of a nebulizer operated with compressed air.

Creosote in the form of a spray as spoken of favorably in one instance, by McPhedran of Toronto, may be useful and not injurious, but I do not believe it is so practicable as the dry vapors when they are persistently employed.

I consider in summer that a sojourn at sulphur springs with treatment there employed—inhalations, baths, drinking the water specially indicated. The mere breathing of the air continuously, near and around sulphur springs, is of itself curative. Sharon, Richfield Springs, N. Y., White Sulphur Springs, W. Va., are resorts which may be advantageously selected. In later years, more than one surgeon has tried to bring about a cure of this wretched disease by surgical methods. I have yet to see, or read of, an instance, in which operatory treatment has been, to my mind, successful in effecting an absolute cure. A few cases may be ameliorated, and operation is permissible, when other rational means have failed.

Up to the present time, I would only willingly indorse an operation, where a large, relatively isolated cavity was accurately diagnosed and not far removed from the surface of the lung. In such a case, I would wish to have the neighboring costal and pulmonary pleura closely adherent one to the other. If that were the condition, sufficient incision with or without the resection of a portion of one or two ribs, and the introduction of a drainage tube through which suitable medical fluids could be frequently injected, might bring about locally much improvement.

Clinically to sum up: In fetid bronchitis we have a rare and very obstinate and distressing affection. In its management, I know of nothing better than what I have advised. It may take many months to effect a notable and favorable result, but if my treatment is persisted in, it will ultimately make life bearable to oneself and others, even though it does not succeed in producing an absolute cure.

Chronic Myelemia with Complete Dislocation of Spleen.—A. J. Hall reports the case of a woman who was first seen by a surgeon on account of an abdominal tumor, which, arising in the pelvis, reached upward above the navel. It was smooth, firm, and rounded, with a completely free edge above. A pelvic tumor was diagnosed and laparotomy performed. The tumor was found to be an enormous spleen completely dislocated and resting on the floor of the pelvis. Fortunately, no attempt was made at removal. A blood examination followed and showed the true nature of the case which ran an ordinary course, apparently not aggravated by the surgical interference.—*Proceedings of the Royal Society of Medicine.*

THE MECHANISTIC CONCEPTION OF DEMENTIA PRECOX

THERE is hardly a greater and more serious problem confronting the psychiatrist and society in general than that of dementia prevox. It is a problem which has baffled the students of mental disease, and, in spite of the considerable progress which has been made in recent years in the field of psychiatry, we still find the most diverse opinions concerning the nature of that mysterious affection. The great battle which has for some time been going on and which is waxing more interesting at present is concerned with the mechanistic conception of dementia precox. One school adheres to its psychological origin and nature, maintaining that the somatic manifestations are not primary but secondary. Another school insists that the psychological manifestations are merely secondary and are but the end results flowing out of certain definite organic changes, the physical disease being primary and essential, and producing, by its associated disorders, the glaring objective mental picture. Since this standpoint is of the greatest importance for an understanding of the real nature and cause of the condition, and hence for possible therapeutic attack of a physical nature, it will be interesting to consider briefly the arguments of those favoring the mechanistic view. Some of the foremost phychiatrists have insisted that dementia precox is due to some as yet unknown toxemia, and it is the toxic nature of this disease which is stressed by the writers who support the mechanistic standpoint. Many papers have appeared in the last few years offering evidence in support of this view. The amount of evidence being accumulated is rapidly increasing, and the number of adherents to these ideas will no doubt increase in proportion. This will mean more earnest and intensive work, with findings that will be of the greatest value in one or the other direction—of a positive or a negative nature.

The members of the mechanistic school contend that dementia precox, when fully established, is a pluriglandular affection in which the sex glands and two or three other glands of internal secretion are undergoing dystrophic processes, similar to the changes found in the thyroid and thymus of exophthalmic goiter and in the other endocrinous glands of individuals affected by other pluriglandular dystrophies. The case for dementia precox as a pluriglandular disease is well summed up by Bayard Holmes (*Chicago Medical Recorder*, Vol. XXXVII, No. 3), who has followed the trend of the organic concept and has accumulated much evidence in its behalf. The best evidence to be found is presented to us by the application of the Abderhalden reaction to dementia precox and allied disorders. It has been demonstrated that the Abderhalden defensive ferment reaction shows conclusively the existence of processes of degeneration and dysfunction in the pluriglandular system, the sex glands in particular, in more than two-thirds of the cases of dementia precox, whereas, in marked contrast, such disturbances of these organs are absent in the manic depressive psychosis and in mentally normal persons. There is evidence that the blood-pressure raising apparatus is disturbed, since the blood pressure is usually found to be low in the early stages, and the injection of adrenalin in quantities sufficient to raise the blood pressure of an adult from forty to eighty millimeters of mercury has little or no effect in patients suffering from dementia precox. Furthermore, contrary to what is found in normal individuals and in other types of insanity, there is a protracted increase in the number of neutrophiles following the adrenalin injection. The toxicity of the blood, as shown especially by its hemolytic power, seems to be marked. Morphological changes in the blood have been observed during the catatonic stage. The blood has been found to be highly concentrated, and Kahlmeter and others have observed a seeming polycythemia and a relative leucopenia. With any tendency toward betterment there has been noticed a change upon which Lundvall lays particular stress. He calls these blood changes "blood crises," and notes that they occur periodically, apparently as a constant phenomenon, and independent of factors which might lead to increased muscle work or of physical excitement. This blood crisis is characterized by a leucocytosis, chiefly a polynucleosis, associated with a critical and often protracted post-critical eosinophilia. The increased red blood cell count and the decreased white blood cell count with the blood pressure below 100 or rarely as high as 120, gives us, as Holmes states, "a blood picture distinctly significant of a grave toxemia." It is also argued that the errors of metabolism, which need not be enumerated here, but which have been detected in dementia precox, are significant of a peculiar and uniform toxemia, particularly when compared with manic depressive insanity and general paresis. Certain studies have disclosed some gross and histopathological changes of the brain and of the ductless gland system, including the thyroid and thymus, the parathyroid glands, the adrenal glands, and the sex glands. This field has, up to date, been but little explored and the findings cannot be stated with absolute conviction and certainty, but the observations so far published have been suggestive and must lead to more thorough attack in this direction. Post-mortem studies of the ductless glands should become a part of the routine in future work.

It is seen from the above that, as Holmes suggests, future studies should include metabolic stud-

ies, Abderhalden reaction studies, blood studies, blood-pressure studies, and reaction studies to determine the functional competency of the ductless glands, particularly the adrenal and the sex glands. It is asserted that not only is there laboratory and symptomatic evidence as well as morphological and histological evidence of the existence of pluriglandular disturbances in dementia precox, but also that comparison of dementia precox with other pluriglandular conditions lends added support to the contention of the mechanistic basis of the prevalent insanity of youths. The knowledge gained from the studies into the origin of other pluriglandular conditions, in addition to other findings, seems to the mechanists to point strongly to peripheral infection or alimentary intoxication as the source of dementia precox. As yet very little research has been made along this line. However, Holmes, Dercum, and others hold that we must accept the probability that the etiology of dementia precox is at least similar to that of the other ductless-gland disorders. In fact many of the workers now accept as proven the toxic etiology of dementia precox, and point to the ductless-gland changes, particularly the dysfunction of the genital glands, as proof of the primary toxic nature of this mysterious disease which lays hold of so many adolescents at the critical period of their lives. Already a method of treatment has been elaborated which has for its object the increase of the leucocytes in the blood of dementia precox patients, with the object of enhancing the resisting power of the individual. A search for possible sources of infection is advocated and various other therapeutic suggestions have been put forward.

Although there is much evidence against this theory, and although there are many battles yet to be fought over many of the problems involved, still the case for dementia precox as a pluriglandular disease is now being pushed to the foreground with such persistence and rapidity that it must at least demand our respectful consideration. It seems very likely that the future will show that there are at least two different types of so-called dementia precox, namely the psychogenetic and somatogenetic types. Be that as it may, the reader should consider the fact that at least in a certain proportion of cases, dementia precox may be the result of a peripheral infection which, as Holmes says, by selective action destroys the chromaffin elements of the adrenal, the sex glands, and profoundly affects the thyroid, the thymus, the parathyroid, and the cranial contents.

THE RESPIRATORY "DEAD SPACE."

A CURIOUS instance of two sets of investigators working on the same theme unknown to each other and reaching the same conclusions at the same time is illustrated by the publication of two papers in the *American Journal of Physiology*, July 1, 1915. The first of these papers by Yandell Henderson, F. P. Chillingworth, and J. L. Whitney on "The Respiratory Dead Space" was ready for publication when Henderson wrote to J. S. Haldane of Oxford, England, describing the results obtained. By return mail the latter replied that he had been at work on the same theme and had obtained practically the same results. A few days later he sent the manuscript of his paper, with the result that this appears in the same number of the above journal under the title, "The Variations in the Effective Dead Space in Breathing."

The "dead space" of the lungs connotes the capacity of the bronchial tree and was estimated by Loewy in 1891 to be 144 c.c. Since 500 c.c. of air is taken in with each inspiration, the amount available for actual ventilation of the pulmonary alveoli is determined by deducting from the volume of inspired air the 144 c.c. that fills the bronchial tree. Zuntz and others regarded this dead space as of an unvarying volume, but it was shown by Siebeck in 1911 that during the hyperpnea of physical exercise the dead space is increased.

Henderson and his collaborators find, from a consideration of the axial flow of gases through tubes and from determinations of the CO_2 content of successive fractions of the expired air, that some alveolar air containing CO_2 in increasing amounts begins to issue from the nose and mouth even in the first 50 c.c. of an ordinary expiration. This shows that the alveolar air diffuses rapidly through the dead space. Even an amount of tidal air much smaller than the capacity of the bronchial tree may afford a considerable gaseous exchange, as in animals during heat hyperpnea. It is found that the dead space expands and contracts passively with the movements of the thoracic walls and lungs. At shallower levels than ordinary breathing the dead space is considerably less than 150 c.c. With deeper breathing it may amount to as much as 600 c.c.; with the deepest breaths it may exceed a liter in volume. It is much more affected by diaphragmatic than by costal movements and is of practically the same volume during rest and exercise. The enlargement of the dead space during hyperpnea is essentially a passive stretching and not an active bronchodilatation. Even at a uniform extent of chest inflation the dead space is continually undergoing active variations in volume, which may at times exhibit a distinct rhythm of a period of several minutes, and which may amount to as much as 30 per cent. of the mean volume of the dead space in quiet breathing.

Of considerable practical significance is the fact that in a close and stuffy room the bronchi are constricted and that a distinct chill constricts them still further. Pleasantly cool fresh air induces bronchodilatation. Experiments in a Turkish bath have shown that during profuse perspiration and cutaneous hyperemia there is a greatly augmented diffusion of CO_2 from the walls of the dead space, which fact indicates a hyperemia of the respiratory passages. As much as one-half of the total CO_2 exhaled by the subject may come from the dead space. In asthmatics the chronic dilatation of the chest stretches the pulmonary passages passively and thus tends to compensate to some extent for their active contraction.

Haldane reaches practically the same conclusions as those above reported. He notes, however, that the "effective" or "virtual" dead space is a physiological and not an anatomical conception, the magnitude of this space depending on the physiological

efficiency of the respiratory surfaces in relation to the supply of venous blood and fresh air. He emphasizes the fact that estimates of the composition of alveolar air from the composition of the mixed expired air on the assumption of a constant dead space are fallacious. Haldane believes that the greater part of the blood which has lost CO_2 directly to the dead space passes to the left side of the heart and that the passive stretching of the dead space occurs principally in the pulmonary infundibula.

THE VITAL STATISTICS OF A COMMUNITY AND THE PERSONAL FACTOR.

It is held by many that in proportion as a nation increases in industrial wealth, so does the population deteriorate. That is to say, the average excellence of the people diminishes. In the first place, the inhabitants of a manufacturing country are for the most part massed together in cities, and this alone tends to bring about a considerable amount of degeneration. In the second place, industrial prosperity affords the opportunity for the workers generally to expend a great deal of money in luxurious living, and in the course of time a comparatively large section of the people will have, in consequence, retrograded physically and mentally. Drink and other forms of vice and dissipation, combined with unhygienic living and unsanitary dwellings, for these invariably go together, will have played their harmful parts, and a no mean portion of the population will have to be denominated as degenerates or as approaching the state of degeneracy. A thriftless, irresponsible, and lazy class will have been evolved.

In Europe, and to a lesser extent on this continent, the social problem is that which bulks most large. The thieves, drunkards, and wastrels of all kinds which confront one in the slums of all cities, are the despair of reformers, and convince them, if there were any doubt on the matter, that it is the personal factor which counts. And it is not only the submerged or more or less submerged tenth which arouses the sociologist, but the decent very poor. It is obvious that where there are extreme poverty, vice, and dissipation, there must be also a great deal of disease. The object of the social reformer is to cope with these conditions. However, the personal factor cannot be disregarded, and as this factor is largely a question of heredity, the problem becomes more complex.

It is an open question as to whether bad environment leads to drink or vice versa. The advanced socialist declares with decision that it is the environment that leads to drink, and that given improved dwellings and manner of living this canker which is eating into the vitals of modern society will be eradicated; whereas others, with as much if not more reason for confidence in their opinions, say that it is bred in the bones to be dissolute.

Dr. W. Robertson, Medical Officer of Health of Leith, Scotland, takes the latter view, and holds that the personal factor is predominant and that although this bad personal factor may be taught in process of time the worth of right living, the process will be slow. In a recent address he asserts that it may be stated without fear of contradiction that alcohol has been the greatest dehumanizing influence in the world's history. It matters little whether it be a question of cause or effect. Any measures, therefore, which promise to save chronic offenders from its baneful blight will be for the good of the race as of the individual. Of course, improved housing is an ameliorating factor; vital statistics have proved this in all civilized countries, and especially in Great Britain. Of all hygienic efforts which have effected so much in reducing the incidence of disease, none has exerted greater power than improving the environment of the poor. It is patent to all that the provision of airy, decent dwellings, with a sufficiency of air space around, cannot but be a long step in the direction of advancing the standard of health of a community. Education again can do a great deal toward improving the individual from all points of view. Still, the personal factor must always be looked upon as the most important of all.

Ergotism from War Bread.

At present we may speak of two kinds of war bread in the belligerent countries of Europe. One is due to Government fiat and is standardized. The other is the result of actual or alleged stringency in bread makings, and is made of inferior or falsified materials. It is quite conceivable that "spurred rye" may find its way into bread, as has often happened even in peace times. At a session in April of the Royal Imperial Medical Society of Vienna (*Berlincr klinische Wochenschrift*, May 17) Fuchs presented a soldier with convulsive ergotism. The man had lived while in Russian Poland on the native bread. The disease picture was that of severest tetany. There was, however, dry gangrene of the great toes, which at first suggested freezing, but although the patient had lived in the trenches the weather had not been cold. The author now investigated the feces and found ergot in abundance. The bread had been very dirty and had evidently contained ergot in large quantities. Recovery was spontaneous. The author regards epidemic tetany as a mild form of ergotism, and says it often develops after eating bread made with contaminated flour.

Bread or Beer?

Any question as to whether barley should be made into beer or bread in order to get the best food value would hardly be seriously agitated in the United States, even although barley is not much used as a breadstuff. It is otherwise in Germany, where beer is regarded as a sort of liquid bread, the alcohol content of which—when beer is used within dietetic limits—is not held to pass beyond the limits of combustibility. This "burning question" was recently made the subject of a session of the Anti-Alcoholic Society of Physicians of Munich (*Muenchener medizinische Wochenschrift*, May 25). Theilhaber, the speaker, made the following points in favor of bread, or rather, against beer as an article of diet: The value of beer calories is supported by one-sided arguments; no regard is had to the toxic action of alcohol; brewing leaves out the vitamines and mineral constituents of the other coatings of the grain. Even at best beer nutriment

represents a luxus consumption, for doubtless those who consume it do not require these extra calories. The sense of the meeting was that beer brewing ought to cease until the war is over. If this cannot be brought to pass then brewing should be minimized.

News of the Week.

Death Rate in New York City.—The Department of Health reports 1,376 deaths in this city during the week ending July 17, an increase of 90 over the number reported during the corresponding week of last year. The increase in the number of deaths was evenly distributed among all age periods, the group under five years showing the largest proportion. In this group there was an increase of forty-three deaths. In the group under one year of age there was an increase of seven deaths. The death rate for the first twenty-nine weeks of 1915, is 13.94, as compared with 14.42 for the corresponding period of last year.

Medical License Examinations.—As a result of the recent examination of applicants for license to practise medicine in the State of Pennsylvania 224 passed successfully and were granted licenses and twenty-four failed.

Dr. G. M. Williamson, secretary of the North Dakota State Board of Medical Examiners, reports the results of the recent examinations. Eleven candidates took the written examination, and of these, seven were successful; ten applied for the practical and oral examination and for reciprocity certificates, and of these, eight were successful. Five applicants were granted reciprocity licenses to practise without further examination.

Forty-nine of the sixty-five applicants for medical and osteopathic licenses in the State of Washington passed the examination held at Seattle in June. Of the forty-nine successful applicants forty were licensed to practise medicine and nine to practise osteopathy. Included in the list of successful doctors was the secretary of the State board of health.

Typhus and Cholera Epidemic Abating.—The American vice-consul at Belgrade has reported by cable to the State Department that "the spread of typhus in Montenegro is controlled. The epidemic is practically over there now. There are very few scattered cases. Typhus and other infectious diseases in Serbia continue to decrease rapidly. Cholera towns gradually being cleaned." The dispatch added that an appropriation of $10,000 for use in Serbia would be ample for control of infectious disease during the next two months, and that certain permanent improvements could be made with a similar amount. The Red Cross has approximately $10,000 available for that purpose. It has previously given $30,000. The Rockefeller Foundation gave nearly $100,000, and a Serbian committee contributed $10,000.

A Baby Hospital in Serbia.—The American Red Cross announces that it has arranged to establish a baby hospital in Serbia to be supported by the Red Cross of this country and to be manned by American doctors and nurses. The hospital will be known as the Mabel Grouitch Baby Hospital, in recognition of the Red Cross activities of Mme. Slavko Grouitch, wife of the Serbian Under Secretary for Foreign Affairs, who is an American woman. Two physicians who will have charge of the hospital, Drs. Louise Taylor Jones of Washington, and Catherine H. Travis of New Britain, Conn., sailed last week on the Greek steamship *Constantinos V*, and two nurses for the hospital will sail next week.

Charitable Bequests.—By the will of the late Mary Van Beil of Marion, Pa., the sum of $5,000 is bequeathed to each of the following Philadelphia institutions, for the endowment of a free bed: Methodist Episcopal Hospital, Jewish Hospital, and Episcopal Hospital.

The will of the late Annie M. Wilson of Philadelphia contains a contingent bequest of $15,000 to the Jefferson Hospital, for the maintenance of three free beds to be known as the "Wilson Memorial Beds, for the benefit of reduced gentlemen."

Examination for Resident Physician.—The Civil Service Commission of Philadelphia announces an examination to be held on August 13 for the position of resident physician under the Bureau of Health of the Department of Public Health and Charities of that city. There are six vacancies and the positions carry a salary of from $600 to $800 a year. The examination is open only to residents of the State of Pennsylvania. The duties of these positions are to give medical assistance to the inmates of the institution to which the physician is assigned and any other duties appropriate to the title which may be assigned. The applicant must be a graduate of a recognized school of medicine and licensed to practise in the State of Pennsylvania. He should have some institutional experience, and preferably be above 25 years of age.

Dr. Mayer Resigns from the Staff of the "Centralblatt für Laryngologie."—In a recent issue we noted that the editor and publisher of the *Internationales Centralblatt für Laryngologie* had removed the name of Sir Felix Semon from the title page, because of his expression of opinion as a naturalized English citizen regarding "Germany's barbarous warfare." As this action destroyed the journal's claim to be international in character, as a protest against the introduction of politics in a scientific journal and in loyalty to a man who has done so much for laryngology, Dr. Emil Mayer of New York City, who for the past sixteen years has been the collaborator for America, has tendered his resignation to the editor of the *Centralblatt*.

Dr. Harold B. Wood of Chicago has been appointed chief of the public health bureau of Topeka, Kan. He received the degree of doctor of medicine from the University of Pennsylvania in 1901, and that of doctor of public health from the same institution in 1910. In Chicago he was in charge of the sanitary and medical inspection of public schools.

Dr. H. S. Baketel of this city, editor of the *Medical Times*, has been appointed professor of hygiene and public health in the Long Island College Hospital, Brooklyn.

Dr. Richard Kovacs of this city has removed to 223 East Sixty-eighth Street.

Regulating the Sale of Proprietary and Patent Medicines.—The Louisiana State Board of Health has adopted verbatim the ordinance enacted by the Board of Health of the City of New York in December last, regulating the sale of proprietary and patent medicines. This ordinance, which will become effective in New York City on December 31, 1915, requires either the registration of the names of ingredients of all proprietary or patent medicines with the Board of Health, or, in lieu thereof, the printing of the name of each ingredient "conspicuously, clearly, and legibly in English, on the outside of each bottle, box, or package in which the medi-

cine or medicinal compound is held, offered for sale, sold, or given away." The weekly *Bulletin* of the Health Department says it is advised that Cincinnati has under consideration the enactment of this same ordinance, and that similar legislation is being considered in Indiana, Minnesota, and other Western States.

Committee of American Physicians for the Aid of the Belgian Profession.—Dr. F. F. Simpson, treasurer, 7048 Jenkins Arcade Bldg., Pittsburgh, Pa., reports the following contributions for the week ending July 24, 1915:

Dr. Charles N. Dowd, New York, N. Y.	$25.00
Dr. Emil Lofgren, Rockford, Ill.	5.00
Columbia Medical Society, Columbia, S. C.	20.00
Receipts for the week ending July 24	$50.00
Previously reported receipts	7,700.84
Total receipts	$7,750.84

Obituary Notes.—Dr. James Albert Bennett of New York, a graduate of the New York Homeopathic Medical College and Hospital in 1871, a member of the American Institute of Homeopathy and the New York County Homeopathic Medical Society, and for the last twelve years treasurer of the Consolidated Gas Company of New York, died at his home on July 11, aged 72 years.

Dr. Thomas Aloysius Maloney of Springfield, Mass., a graduate of the New York University Medical College in 1898, and a member of the Massachusetts Medical Society and the Hampden District Medical Society, died at the home of his mother in New Britain, Conn., on July 13, aged 40 years.

Dr. Lewis H. Adler of Philadelphia, a graduate of the University of Maryland School of Medicine, Baltimore, in 1859, and of the Jefferson Medical College, Philadelphia, in 1871, died at the Methodist Hospital, Philadelphia, on July 15, aged 73 years.

Dr. Isidor Zippert of New York, a graduate of the New York University Medical College in 1898, and a member of the East Side Medical Society, died at his home after a long illness, on July 14, aged 39 years.

Dr. Anton Theodore Remer of Dallas, Tex., a graduate of the Barnes Medical College, St. Louis, in 1900, died at his home on July 2, aged 53 years.

For the Promotion of International Morality.—We are requested to publish the following appeal:

To the Men and Women Engaged in Medical Practice and the Advancement of the Medical Sciences: The present horrible war among civilized nations has brought out impressively certain sad facts: that although there are civilized *individual* nations, we are still very far from having a civilized humanity—there is an abyss between *intra*national and *inter*national morality; that, no matter how cultured and enlightened nations may be, they still settle their international differences by brute force, by maiming and killing their adversaries; and, finally, that the present high development of science and invention in individual nations only serves to make the results of this war more destructive than any other in history.

The war has demonstrated, however, one encouraging fact, namely, that among all the sciences and professions, the medical sciences and medical practice occupy an almost unique relationship to warfare, and that, among all the citizens of a country at war, medical men and women occupy a peculiar and distinctive position.

No discovery in medical science has been utilized for the purpose of destroying or harming the enemy. Medical men in each of the warring countries are as courageous, as patriotic, as any other citizens, and are as ready to die or to be crippled for life in the service of their country as any other class of their fellow countrymen. But their services, however, consist in ministering to the sick and to the injured and in attending to their sanitary needs. Furthermore, they often risk their lives by venturing into the firing line to bring the injured to places of safety and to attend to their immediate needs. *In these heroic and humanitarian acts friend and foe are treated alike.* Finally, the majority of the members of the medical profession and of the medical journals of the neutral as well as of the warring countries abstain from public utterances that might be grossly offensive to any of the belligerent nations.

These facts—this advanced moral position in international relations which medicine and its followers are permitted to occupy in all civilized nations, ought to be brought to the full consciousness of the men and women engaged in the medical sciences or in medical practice. Such a realization could not fail to have an elevating influence upon the medical profession itself, and would probably exert a favorable influence upon the development of international morality in general.

At the dawn of history, medical men were frequently also the exponents of philosophy and morals. In the middle ages, when knowledge became specialized, medical men more and more devoted their activity exclusively to medical practice. Because of its inefficiency at that time, medicine lost its prestige. In recent times, however, medicine is becoming an effective science; one marvelous discovery has followed another, and the efficiency of medical practice has been rapidly increasing. Medicine makes habitable to man hitherto uninhabitable parts of the world. It prevents disease; and, with increasing theoretical and practical efficiency, medicine is learning to alleviate and cure disease and injuries. Medical sciences and medical men have steadily risen in the esteem of civilized mankind. *May not the medical sciences and medical men become again the standard bearers of morality, especially of international morals?*

To accomplish these objects, it is proposed to organize as large and effective an Association as may be possible of men and women engaged in the medical sciences or in medical practice under the name of The Medical Brotherhood for the Furtherance of International Morality.

It is obvious that such a Brotherhood could not exercise an important influence at once. But our modest expectation for prompt results should not prevent us from attempting now to take the first step in the right direction. Many important results have often had small beginnings.

A Committee of Physicians and Medical Investigators request you herewith to enroll as a member, and to declare your willingness to endorse and support the moral standard which the medical profession generally upholds when called upon to perform its patriotic duties in an international strife.

It should be expressly understood that it is not the object of the proposed Brotherhood to influence the feelings and views of any one regarding the problems involved in the present war. It is desired merely to bring to the full consciousness of the members of the medical profession the exceptional moral position which all civilized nations, even while at war, *permit* and *expect* medical men to occupy at least as long as they remain in the medical profession and act in this capacity. This consciousness cannot fail to elevate the moral standards of physicians. Furthermore, after the close of the present war, the Brotherhood could without doubt facilitate the reunion of the members of the medical profession of all the nations which are now at war and increase good feeling among them. A humanitarian body such as this proposed Brotherhood, if already in existence and ready for service, might and could be of the greatest usefulness in many ways.

Medical readers of the above appeal are requested, if they are so inclined, to enroll as members. There is no membership fee, but voluntary contributions for the purpose of upholding the organization, distribution of literature, etc., will be gratefully accepted. Enrollment and contributions are to be sent to the Medical Brotherhood in care of Dr. S. J. Meltzer, 13 West 121st street, New York City.

The following is a list of the officers and members of the advisory committee of the Medical Brotherhood:

EXECUTIVE COMMITTEE (Residents of the City of New York): *President*, Dr. S. J. Meltzer, Member Rockefeller Institute; *First Vice-President*, Dr. Rufus Cole, Director Rockefeller Hospital; *Second Vice-President*, Dr. S. Josephine Baker, Director Dept. of Child Hygiene; *First Secretary*, Dr. Wm. J. Gies, Professor of Biological Chemistry, Columbia University; *Second Secretary*, Dr. Harlow Brooks, Professor of Clinical Medicine; *Treasurer*, Dr. Robert T. Morris, Professor of Surgery, Post Graduate Medical School; *Council*, Drs. Abraham Jacobi; Robert Abbe, Surgeon to St. Luke's Hospital; John Winters Brannan, President Medical Board, Bellevue Hospital; J. A. Fordyce, Professor of Dermatology, College of Physicians and Surgeons; Nellis B. Foster, Assistant Professor of Medicine, Cornell University Medical School; S. S. Goldwater, Commissioner Dept. of Health; Graham Lusk, Professor of Physiology, Cornell University, Medical School; William H. Park, Professor of Bacteriology, Univ. & Bell. Medical College; John Allen Wyeth, President New York Polyclinic.

HONORARY PRESIDENTS: Drs. Russell H. Chittenden, Director, Sheffield Scientific School, Yale University, New Haven; W. T. Councilman, Professor of Pathology, Harvard Medical School, Boston; W. C. Gorgas, Surgeon-General of the Army, Washington, D. C.; W. S. Halsted, Professor of Surgery, Johns Hopkins Medical School, Baltimore; W. H. Howell, Professor of Physiology, Johns Hopkins Medical School, Baltimore; Abraham Jacobi; W. W. Keen, President International Surgical Congress, President American Philosophical Society, Philadelphia; Edward L. Trudeau, Saranac Lake, New York; James Tyson, Professor of Medicine, Emeritus, University of Pennsylvania, Philadelphia; Victor C. Vaughan, Professor of Hygiene and Physiological Chemistry, Ann Arbor; William H. Welch, President National Academy of Sciences; Professor of Pathology, Johns Hopkins Medical School, Baltimore.

HONORARY VICE-PRESIDENTS: Drs. J. J. Abel, Professor of Pharmacology, Johns Hopkins Medical School, Baltimore; Herman M. Biggs, Commissioner, State Board of Health, New York City; Frank Billings, Dean, Rush Medical College, Chicago; Clarence John Blake, Professor of Otology, Emeritus, Harvard Medical School, Boston; W. B. Cannon, Professor of Physiology, Harvard Medical School, Boston; W. H. Carmalt, Professor of Surgery, Emeritus, Yale University Medical School, New Haven; George Dock, Professor of Medicine, Washington University, Medical School, St. Louis; James Ewing, Professor of Pathology, Cornell University Medical School, New York City; Alice Hamilton, Expert on Occupational Diseases, Federal Bureau of Labor Statistics, Washington; L. Hektoen, Professor of Pathology, Rush Medical College, Chicago; Howard A. Kelly, Professor of Gynecology, Johns Hopkins Medical School, Baltimore; Robert G. LeConte, President, American Surgical Association, Philadelphia; Rudolph Matas, Professor of Surgery, Tulane University, New Orleans; William J. Mayo, Rochester, Min.; Charles K. Mills, Professor of Neurology, University of Pennsylvania, Philadelphia; John B. Murphy, Professor of Surgery, Northwestern Medical School, Chicago; E. L. Opie, Professor of Pathology, Dean, Washington University Medical School, St. Louis; Charles A. Powers, Professor of Clinical Surgery, Emeritus, University of Colorado, Denver; W. L. Rodman, President American Medical Association, Philadelphia; G. E. deSchweinitz, Professor of Ophthalmology, University of Pennsylvania, Philadelphia; Henry Sewall, President, Association of American Physicians, Denver; F. C. Shattuck, Professor of Medicine, Emeritus, Harvard Medical School, Boston.

ADVISORY COMMITTEE: Drs. Isaac Adler, Consulting Physician, German Hospital, New York City; Fred H. Albee, Professor of Orthopedic Surgery, New York City; Carl L. Alsberg, Chief of Bureau of Chemistry, Washington, D. C.; James M. Anders, Professor of Medicine, Medico-Chirurgical College, Philadelphia; John F. Anderson, Director, Hygienic Laboratory, Washington, D. C.; John Auer, Associate Member, Rockefeller Institute, New York City; Edward R. Baldwin, Saranac Lake, New York; Helen Baldwin, Attending Physician, New York Infirmary for Women and Children, New York City; J. C. Bloodgood, Associate Professor of Surgery, Johns Hopkins Medical School, Baltimore; George Blumer, Professor of Medicine, Dean, Medical School, Yale University, New Haven; Joseph A. Capps, Associate Professor of Medicine, Rush Medical College, Chicago; A. J. Carlson, Professor of Physiology, University of Chicago, Chicago; Henry Dwight Chapin, Professor of Medicine, New York Polyclinic, New York City; Henry A. Christian, Professor of Medicine, Harvard Medical School, Boston; Frank S. Churchill, Associate Professor of Pediatrics, Rush Medical College, Chicago; S. Solis Cohen, Professor of Clinical Medicine, Jefferson Medical College, Philadelphia; C. G. Coakley, Professor of Laryngology, Univ. & Bell. Medical College, New York City; Warren Coleman, Professor of Clinical Medicine, Cornell Medical School, New York City; Joseph Collins, Neurologist, Neurological Institute, New York City; T. S. Cullen, Associate Professor of Gynecology, Johns Hopkins Medical School, Baltimore; Elizabeth M. Cushier, New York City; Samuel G. Dixon, Commissioner, State Board of Health, Philadelphia; Theodore Diller, Associate Professor of Clinical Neurology, University of Pittsburgh, Pittsburgh; I. Dyer, Dean, Tulane University, New Orleans; F. X. Dercum, Professor of Nervous and Mental Diseases, Jefferson Medical College, Philadelphia; Harold C. Ernst, Professor of Bacteriology, Harvard Medical School, Boston; D. L. Edsall, Professor of Clinical Medicine, Harvard Medical School, Boston; C. A. Elsberg, Surgeon, Mt. Sinai Hospital, New York City; Henry L. Elsner, Professor of Medicine, University of Syracuse, Syracuse, New York; Joseph Erlanger, Professor of Physiology, Washington University, Medical School, St. Louis; Charles H. Frazier, Professor of Clinical Surgery, University of Pennsylvania, Philadelphia; T. B. Futcher, Associate Professor of Medicine, Johns Hopkins Medical School, Baltimore; Henry B. Favill, Professor of Clinical Medicine, Rush Medical College, Chicago; Fielding H. Garrison, Editor *Index Medicus*, Washington, D. C.; Arpad G. Gerster, Professor of Clinical Surgery, Columbia University, New York City; Joel E. Goldthwait, Orthopedist, Boston; Virgil P. Gibney, Professor of Orthopedic Surgery, College of Physicians and Surgeons, New York City; H. A. Hare, Professor of Therapeutics and Diagnosis, Jefferson Medical College, Baltimore; R. A. Hatcher, Professor of Pharmacology, Cornell University Medical School, New York City; I. Minis Hays, Secretary, American Philosophical Society, Philadelphia; F. P. Henry, Professor of Medicine, Women's Medical College of Pennsylvania, Philadelphia; Yandell Henderson, Professor of Physiology, Yale University, New Haven; A. W. Hewlett, Professor of Medicine, Ann Arbor; James B. Herrick, Clinical Professor of Medicine, Rush Medical College, Chicago; C. F. Hoover, Professor of Medicine, Western Reserve University, Cleveland; J. W. Holland, Professor of Physiological Chemistry, Emeritus, Jefferson Medical College, Philadelphia; John Howland, Professor of Pediatrics, Johns Hopkins Medical School, Baltimore; Reid Hunt, Professor of Pharmacology, Harvard Medical School, Boston; Woods Hutchinson, New York City; Holmes C. Jackson, Professor of Physiology, New York and Bellevue Medical College, New York City; Philip Mills Jones, Editor *California State Medical Journal*, San Francisco; George W. Jacoby, President Neurological Society, New York City; Theodore C. Janeway, Professor of Medicine, Johns Hopkins Medical School, Baltimore; Frederic Kammerer, Professor of Clinical Surgery, College of Physicians and Surgeons, New York City; Frederick S. Lee, Professor of Physiology, Columbia University, New York City; E. Libman, Physician to Mt. Sinai Hospital, New York City; Howard Lilienthal, Surgeon to Mt. Sinai Hospital, New York City; Warfield T. Longcope, Professor of Medicine, Columbia University, New York City; F. J. Lutz, Professor of Clinical Surgery, Washington University Medical School, St. Louis; Hanau W. Loeb, Dean, St. Louis University Medical School, St. Louis; Walter Mendelson, Trustee, Columbia University, New York City; Rosalie S. Morton, President, New York State Woman's Medical Society, New York City; W. G. MacCallum, Professor of Pathology, Columbia University, New York City; L. B. Mendel, Professor of Physiological Chemistry, Sheffield Scientific School, New Haven; Chas. H. Mayo, Rochester, Minnesota; James F. McKernon, President, Post Graduate Medical School, New York City; Joseph L. Miller, Associate Professor of Medicine, Rush Medical College, Chicago; Albert P. Mathews, Professor of Physiological Chemistry, University of Chicago, Chicago; Ward J. MacNeal, Director, New York Post Graduate Hospital, Medical School, New York City; F. G. Novy, Professor of Bacteriology, University of Michigan, Ann Arbor; Albert J. Ochsner, Professor of Surgery, University of Illinois, Chicago; G. M. Piersol, Editor *American Journal of the Medical Sciences*, Philadelphia; W. M. Polk, Director, Cornell University Medical School, New York City; W. A. Pusey, Professor of Dermatology, University of Illinois, Chicago; Stewart Paton, Neurologist, Princeton, New Jersey; Richard M. Pearce, Professor of Experimental Medicine, University of Pennsylvania, Philadelphia; Joseph H. Pratt, Harvard Medical School, Boston; J. J. Putnam, Professor of Neurology, Emeritus, Harvard Medical School, Boston Howell T. Pershing, Professor of Neurology, University of Colorado, Denver; David Riesman, Professor of Clinical Medicine, University of Pennsylvania, Philadelphia; M. Rosenau, Professor of Preventive Medicine, Harvard Medical School, Boston; Beverley Robinson, Professor of Medicine, Emeritus, University and Bellevue Medical School, New York City; B. Sachs, Neurologist, Mt. Sinai Hospital, New York City; P. A. Shaffer, Professor of Biological Chemistry, Washington University Medical School, St. Louis; C. G. Stockton, Professor of Medicine, Buffalo Medical College, Buffalo; Thomas L. Stedman, Editor MEDICAL RECORD, New York City; Torald Sollmann, Professor of Pharmacology, Western Reserve University, Cleveland; Allen J. Smith, Professor of Pathology, Dean, University of Pennsylvania, Philadelphia; Winford H. Smith, Superintendent, Johns Hopkins Hospital, Baltimore; Frank F. Simpson, Pittsburgh; W. T. Sedgwick, Professor of Biology, Massachusetts Institute of Technology, Boston; Mabel Ulrich, Minneapolis, Minnesota; Ap Morgan Vance, Louisville, Kentucky; Martha Wollstein, Associate, Rockefeller Institute, New York City; George B. Wallace, Professor of Pharmacology, New York University, Medical School, New York City; J. Whitridge Williams, Dean, Johns Hopkins Medical School, Baltimore; J. C. Wilson, Professor of Medicine, Emeritus, Jefferson Medical College, Philadelphia; Hiram Woods, Professor of Ophthalmology, University of Maryland, Baltimore; Jonathan Wright, New York City; H. Gideon Wells, Professor of Pathology, University of Chicago, Chicago; Ray L. Wilbur, Professor of Medicine, Dean, Leland Stanford Junior University, San Francisco; Richard Weil, Assistant Professor of Experimental Therapeutics, Cornell Medical School, New York City

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

HEALTH OF THE SOLDIER—RESEARCH COMMITTEE—SALVARSAN AND ITS SUBSTITUTES—NEW HOSPITAL—OBITUARY.

LONDON, July 9, 1915.

THE Health of the Soldier was the subject to which Dr. F. M. Sandwith devoted his Chadwick lectures, and a very appropriate subject, you may think, in a time of warfare waged on the present scale. The medical dangers of the campaign have declared themselves thus early, and have followed as usual the unsanitary conditions. The tetanus bacillus is present so constantly in the intestines of horses and cattle that it is regarded by many as a normal inhabitant whence the soil and the water are so liable to contamination. Sir George Makins, who was in the South African War, is now consulting surgeon with the forces, and writes from the field:

"One may well look back with envy to the clean soil of the Veldt, much as the dust was then regarded as a bugbear." The high cultivation carried on in France and Belgium has kept up a constant source of the bacilli from the manure so freely employed. In consequence tetanus is notoriously common, for the slightest scratch may admit the organism. Dr. Sandwith mentioned that the number of cases diminished at once when the troops pushed further into Belgium among sandy, barren dunes. He goes on to say that, judging by laboratory experiments on animals, the immunity conferred by antitetanic serum is transitory. It begins to diminish after about a fortnight, and disappears altogether in six or seven weeks. When a bruised wound is soiled with earth, he says it is well to inject an ounce of serum, followed by half-ounce doses weekly until the danger period has passed.

The British regulation treatment of gunshot wounds in the present campaign is: First field dressing of pad of gauze, etc., applied by surgeon, comrade, or patient himself; on reaching field ambulance this is changed, patient taken to clearing hospital, where wound is cleansed, if necessary, and iodine paint freely used. When needful this dressing is repeated during the journey in the ambulance train to the base. Since November an injection of serum has been given as a precaution at the clearing hospital or earlier. Gangrene was next considered by the lecturer, which, he said, was caused by a similar soiling of a wound by dirt, containing in this case the bacillus of malignant edema.

The various forms of gangrene now so rare were not so fifty years ago, and the lecturer thought it was well to be reminded occasionally of our debt to Pasteur and Lister, who disposed of the idea that wound fever and hospital gangrene were spontaneously generated. Before their day gangrene was looked upon as an event of inflammation—a complication which the surgeon could not foresee or prevent. One hundred and fifty years ago there was a great belief in cauterizing by fire, boiling liquids, or disinfectants. It was also thought that wounds should be kept from the air and not touched by hands or instruments, but this gave place to the era of poultices, dressings of old linen, etc., and ointments. An occasional protest was made, but no one saw the reason for cleanliness, and the death rate increased. The danger of surrounding impurities, dirty hands, dressings lying about on filthy tables, and so on, had not occurred to the surgeon. In the operating theater he wore his dirtiest coat, stained with blood and grossly infective matter. To Pasteur's discovery of organic germs in the air and everything unsterilized, modern surgery owes its success. Lister's genius in 1867 applied this knowledge to wound infection. Result: the antiseptic and then the aseptic methods. In 1887 Pasteur discovered the gangrene bacillus—a strict anaerobe, therefore not infecting superficial wounds, but multiplying in living tissues when introduced deeply beneath the skin. Shell wounds in this war have been very destructive in this way, the external aperture being small comparatively, but leading to extensive injury, difficult or impossible to cleanse, necessitating removal of tissues under the skin. The lecturer gave a brief account of his only experience of hospital gangrene in the Russo-Turkish War, when the Greek and native doctors had no disinfectants except quicklime in basins standing on the floor. This old-fashioned hospital gangrene, a complication of septicemia due to dirt, once so common, does not resemble the gas gangrene, of which the bacillus has been recognized and is a traumatic infection from the contaminated soil. It has been found in this war that free exposure to the air, and so to oxygen, gives excellent results, and some of our wounded are being treated in open-air shelters. The patients in the trenches do well in almost any illness from wounds to pneumonia. At Versailles general hospital with 1000 beds, antigangrene vaccine in daily doses for a week has given great success.

Frostbite next occupied Dr. Sandwith's attention, as likely to attack troops as soon as the cold weather sets in. It appeared among those engaged in the present contest as early as November, but Dr. Sandwith's personal experience with it was in the Russo-Turkish War, and he described the Arab soldiers stumbling along in the snow, their hands lost to sensation as they thrust them into the flames of the campfires. In January (1878) eighteen of Baker Pasha's Turkish sentries were frozen to death in one night, and orders were given to change every quarter of an hour. Chilblain is only the first stage, and water-bite, which some are talking about as coming from the trenches, is the same malady.

The lecturer also noticed that form of nervous exhaustion which so constantly arises during war or follows it, for which Weir Mitchell's rest cure is the remedy. He then referred to the impossibility of maintaining cleanliness in a prolonged campaign where clean men may come into contact with others from filthy homes, and vermin are apt to find a way into the camp, and by increasing in vast numbers, worry the men day and night; worse still, they may be carriers of infectious diseases. They are the constant accompaniments of all armies, and it has been said more dreaded than bullets by most officers.

The Medical Research Committee, under the authority of the Local Government Board, has so far exercised a certain control over the sale of salvarsan and the substitutes proposed for it. The committee satisfied itself that French and English preparations were quite equal in purity and efficacy to the original products. It is known that unfavorable results have sometimes followed the administration of the German product, some actual fatalities. Various suggestions have been made as to the cause, but none of them can claim much support. It is now desired that the committee should have more records of the experience of those who have been employing salvarsan or its substitutes clinically. These, compared with laboratory investigations, may settle whether any additions or modifications of the system hitherto employed are desirable. In making such reports as these it is of great importance that full details be given as to the dosage, the exact preparation employed, and the precautions taken to secure purity of the water or other solvent, as well as of the drug itself. As to the last point, comparisons should be confined, at any rate at first, to portions of the same sample, and when that is exhausted to specimens of the products of the same manufacturer.

Major Ffrench, R. A. M. C., on June 15 read a paper at the Dermatological Society on the substitutes. He said kharsivan and neokharsivan were the same as salvarsan and neosalvarsan. Billou is a French substitute, apparently the same as novarsenobenzol, though of a somewhat darker yellow. This powder is soluble in water, giving a clear yellow solution. Neokharsivan is a reddish-brown

powder, also readily soluble, tinging the water. Kharsivan is a yellow powder, not so readily soluble, but a clear yellow solution can be obtained by careful procedure. This solution is mixed with a 4 per cent. solution of sodium hydrate. The remedy is used by intravenous injections, and demands special care. The day before the patient is examined, his urine tested, etc., pil. hydr. gr. 4, given in the evening, followed by Epsom salt in the morning. After a light breakfast, tea and bread and butter, the injection is given in the forenoon, and if no after effects occur tea is had in the afternoon, like the breakfast; and the ordinary hospital dinner at 7.30 P. M., if free from fever or stomach derangement. The routine dosage was three such injections at ten-day intervals. Concurrently mercurial injections were used for nine weeks. Major Ffrench said more than one hundred cases, including primary, secondary, and tertiary disease, had been treated with the substitutes. No serious results had followed their use, and they considered them very excellent substitutes and to be safely recommended for the treatment of all forms of syphilis.

A new hospital to accommodate wounded officers has been established with one hundred beds and the possibility of increasing to two hundred.

The death has occurred of Mr. Clement Lucas, member of the council, and late vice-president of the R. C. S. E., at the age of sixty-nine. He had been senior surgeon to Guy's Hospital, and held other important posts.

Surgeon-Major W. F. MacTier, I. M. S. (retired), died on the 19th ult., aged ninety-two.

4. A Case of Pyelonephritis, Complicated by Adeno-Carcinoma and Chyluria. E. T. Gray.
5. Limitations of the Radical Operation for Cervical Cancer of the Uterus. H. T. Hutchins.

1. Cancer and the Physician's Responsibility. — E. Reynolds states that mammary lumps of benign appearance are sometimes unexpectedly malignant. Delay may convert an undoubtedly benign tumor of the breast into a most malignant growth. Any definite chronic lump in a breast should be removed when possible by a non-mutilating operation. Benign growths of the uterus do not necessarily remain benign. There is no sharp line between the benign and the malignant, and the malignant usually arises from the benign.

2. Surgical Treatment of Cancer of Cervix Uteri.— F. Cobb emphasizes the importance of early diagnosis of cancer of the cervix and the fact that the radical abdominal operation cures a large percentage of cases and carries with it in skilled hands no excessive primary mortality. By radical operation is meant the author's modification of the Wertheim abdominal hysterectomy. This consists in the removal of the uterus and a liberal portion of the vagina and as much of the parametrium as possible through a medium abdominal incision after ligation of both internal iliacs, the regional lymphatic glands being removed only if enlarged to sight and palpation. When done by specially trained men the operation should carry with it an immediate mortality of not over 15 per cent. In advanced cases which are inoperable palliative measures should be resorted to for the prolonging of life and the checking of pain and hemorrhage. These objects may be accomplished by the use of the actual cautery with ligation of the internal iliac and ovarian arteries. Curetting should be done because of the chance of forcing cancer cells into the lymphatics. Percy had developed a valuable method of treating advanced cases by means of the cautery. He opens the abdomen in the median line and ties both internal iliac arteries and the ovarian arteries. After this, with his assistant's hand in the abdomen over the uterus, he uses through a special water-cooled vaginal speculum for from thirty to fifty minutes his special cautery at a low temperature, which he calls a "cold iron," the heat of which is not sufficient to char or carbonize the tissue, about 125 Fahr. The author believes that Percy's method is the one of choice in treating border line and advanced cases of cancer of the cervix.

12. An Improved Urethroscope. E. C. Ballenger and Omar F. Elda.

1. The Psychology of Stammering.—G. H. Makuen states that in 1910 he described the causes of stammering as being twofold, predisposing and exciting, the former being probably congenital and often inherited and consisting in an irritable or hyperesthetic condition of the psychomotor mechanisms of speech. The idea advanced was that stammering is a form of aphasia and like the latter, having probably a physical basis which may or may not be demonstrable. Still more lately C. S. Bluemel has characterized stammering as a transitory auditory amnesia.

2. Applications of Duodenal Tube.—I. O. Palefski finds that by the conjoint use of the duodenal and rectal tubes one may introduce into the intestines large amounts of salt solution and oxygen. A liter of sodium chloride, 1.5 per cent.; sodium bicarbonate, 1.5 per cent.; sodium sulphate, 2.5 per cent.; magnesium sulphate, 5 to 6 per cent., will produce a flushing effect upon the intestinal canal. In lower concentrations these will be absorbed and excreted by the kidneys. In higher concentrations they will produce transudation into the intestinal canal and will be discharged from the rectum in nearly twice the quantity introduced. The irrigation may be carried to a point when the rectal flow will appear clear, odorless, bile colored, and neutral, with a marked reduction in the bacterial contents toward the end. By employing varying concentrations of salt solutions, one is able to deplete the body of its fluid and replenish with fresh saline or water with or without nourishing material. Intestinal irrigation should prove valuable in dysentery and ptomaine poisoning. It should dispense, to a great extent, with appendicostomy for lavage of the ileum and cecum. It enables one to study more accurately the digestive and absorptive powers of the intestines. Transintestinal insufflation with oxygen should prove valuable in intestinal fermentation. By introducing barium into the duodenum one can observe under the fluoroscope the peristaltic action of the jejunum, ileum, and cecum.

4. Unsuccessful Adenoid Operations.—W. Brady be-

lieves that repeated attacks of coryza lead eventually to adenoids. In cases of the latter in which it is doubtful whether to urge operation a course of treatment for the accompanying rhinitis may be sufficient. This course of treatment consists in applications to the nasal mucosa of the ordinary iodine-potassium—iodide-glycerin solutions, and regulation of the general hygiene of the patient.

7. **The Prevention of Syphilis.**—A. W. Stillians concludes as follows: 1. The need of an active campaign against venereal disease is pressing. 2. The possibility of eradicating syphilis is demonstrated by the brilliant record of the United States army. 3. A campaign based upon the same principles should be instituted among civilians. 4. Educational efforts can well begin with students, especially medical and dental students. 5. Among legislative measures needed, an act making it a crime knowingly to transmit venereal disease and an act requiring a certificate of health before marriage are important. 6. Prevention by means of the Metchnikoff ointment should be advocated for all those who expose themselves to the dangers of irregular sexual intercourse.

1. Intraspinal Therapy in Syphilis of Central Nervous System.—H. F. Swift notes that intraspinal injections of "autosalvarsanized serum," or serum to which a small amount of salvarsan or mercury is added, is of distinct help in certain cases of tabes and cerebrospinal syphilis. Not all patients with these diseases require intraspinal treatment. Many of them respond well to intravenous injections of salvarsan combined with mercury and iodides properly administered. In other cases the symptoms and abnormal cerebrospinal fluids are not controlled by general therapy, and it is in this class that the author believes the addition of intraspinal therapy to be of value. Both the clinical side and laboratory evidences of active disease should be considered, and any treatment controlled by repeated examinations of the blood and cerebrospinal fluid. Although the treatment of these diseases should be systematic, it should not be so rigid that individual indications should be disregarded. Not infrequently one sees improvement only after active treatment has been discontinued. Others seem to require constant treatment until all evidences of active disease have disappeared. Only by considering all these factors can consistent beneficial results be obtained.

2. The Pupil in Arteriosclerosis.—M. Wiener and H. L. Wolfner have observed a condition of the pupil which seemed always to be associated with patients registering a high blood pressure. A review of the literature and a careful clinical study of a large series of patients seem to confirm the authors' original deductions as to the clinical significance of this sign. Patients afflicted with fundus disease, or with any condition which might interfere in any way with the reaction of the pupil, are not included in the authors' notations. This pupil is found to be larger than the average normal pupil, with a usual minimum size of 4.5 mm. to 5.0 mm. in width, contracts promptly to light stimulus, but immediately returns to the original size and there remains, without the light stimulus having been changed. While it is not claimed that this reaction is pathognomonic of arteriosclerosis with high blood pressure, the authors maintain that its association with arteriosclerosis with high blood pressure is so nearly constant as to make of it a sign that is at least strongly suggestive, and therefore of clinical value.

3. Splenectomy in Pernicious Anemia.—R. I. Lee, B. Vincent, and O. H. Robertson report that the immediate result of splenectomy in a series of five cases of pernicious anemia was a prompt post-operative recovery and a definite remission of the disease in every case. The remissions were much more marked than is usually seen in pernicious anemia. In four of the five cases the red counts rose to from 4,000,000 to 5,000,000. The remissions occurred so constantly that the authors are inclined to attribute them to the operation of splenectomy. The study shows that in spite of marked improvement, the blood picture still exhibits the accepted characteristics of pernicious anemia with the exception of the color index, which has been altered from high to normal or low. Furthermore, in three of the five cases evidence of increased blood destruction was present several months after spenectomy, as shown by the urobilin estimation. These facts one can interpret only as evidence that the disease is not cured. It cannot as yet be stated that the improvement brought about by this means will last longer than the remissions which come spontaneously and which may persist over a period of years. From the very nature of the disease, it will be many years before the exact value of splenectomy can be determined. The only conclusions one may safely draw from these cases combined with the reports of other writers are: (1) Splenectomy is not a very serious operation in pernicious anemia and offers a definite means of inducing a remission. (2) The remission thus brought about is more marked in the majority of the cases than any other known therapeutic procedure.

1. **Trypanosomes.**—Sir David Bruce, in the third of the Croonian Lectures deals with the *Trypanosoma gambiense*, the cause of the notorious "Congo sleeping sickness." This organism was first seen fourteen years ago in the blood of an Englishman employed on the river Gambia in West Africa. This parasite differs markedly from the *Trypanosoma brucei* which causes nagana among the domestic animals and "Nyasaland sleeping sickness" in man. It is difficult to infect the lower animals with the *Trypanosoma gambiense*, whereas the *Trypanosoma brucei* infects most animals with the greatest readiness. The carrier of the former organism is the tsetse fly, *glossina palpalis*, in which the parasite retains its virulence for a period of about 18 hours after it has been swallowed. It then loses its power of infecting animals for about twenty-two days. Recent investigations have shown that the antelope on the shores of Lake Victoria act as a reservoir of the virus of sleeping sickness.

3. **Tuberculous Infection Retained in Books.** — H. Kenwood and Emily L. Dove conclude that there is probably no material risk involved in the re-issue of books recently read by consumptives, unless the books are obviously soiled. Even then the risks are very slight. Nevertheless, it is desirable to provide against a possible risk, however slight. This will be secured if dirty books recently received from houses in which there is a consumptive reader are not re-issued until such books have been either disinfected or placed "in quarantine" in a separate room for the period of a month. It will be desirable to disinfect such a room from time to time. When such books are very dirty they should be withdrawn from circulation. The loss involved would be much reduced in time if the borrower could be temporarily deprived of his right to borrow when a book is brought back in a badly soiled condition. It would be well to demand (upon a printed and gummed slip) the following precautions of all readers: (a) Not to cough into a book; always to cough into a handkerchief. (b) Not to moisten the fingers when reading; the hands should always be dry and clean. (c) Always to keep the book closed when it is not being read. Moist heat is a simple means of destroying the infection of tuberculosis on those library books which are not likely to be injured by such a method. For this purpose it is not necessary that the temperature should reach 100° C., although it should approximate to that; nor that the exposure should exceed 30 min.

5. **Ionization Treatment of Septic Wounds.**—R. McQueen and L. H. Boothby first clean up and syringe the wounds with sterilized water, or preferably with a 4 per cent. solution of sodium salicylate, and if it is necessary to swab the wounds they use sterilized swabs dipped into the solution; after the wound is thoroughly cleaned they plug it firmly and even tightly with sterilized gauze, or ribbon gauze for the small cavities and pockets, soaked in a warm 8 per cent. solution of sodium salicylate. Then there is placed over all a gauze pad soaked in the same solution, and over this is placed a piece of lint, folded four times, saturated with the solution, which lint is pinned to a copper mail chain electrode attached to the positive pole of a galvanic battery, and a current of from 5 to 30 milliampères is passed for at least a quarter of an hour. The chain electrode and pad are removed and a dry piece of gauze is put over the wet dressings with some wool and kept in position by a few turns of a bandage. It is essential to remember the following points in carrying out this treatment: first, no other antiseptic reagent is to be used in the cleaning of the wounds, not even a solution of boric acid, except perhaps peroxide of hydrogen, and even then the wound should be washed out with sterilized water before using the solution of sodium salicylate; secondly, all cavities leading off from the main wound and spaces between broken and splintered bone must be packed with the gauze, and if separate pieces of gauze are used they must all be in contact with the main plug; thirdly, the gauze must be plain, sterilized gauze and must not be prepared with any antiseptic, fourthly, the current should be gradually increased and diminished, and not turned on and off suddenly; and fifthly, the solution of sodium salicylate should be warm.

6. **Nuclear Division and Phagocytic Power.**—F. E. Taylor has compared the various neutrophile leucocytes according to Arneth's classification, with respect to the average number of staphylococci injected. He has found that the neutrophile leucocyte of Class I with undivided nucleus possesses a moderate power of phagocytosis; that this power of phagocytosis reaches a maximum in the leucocyte of Class II with bipartite nucleus and then progressively diminishes as the nuclear division increases, being lowest in the cells of Class V with multipartite nuclei. It would therefore appear that by taking phagocytic power as an indication of functional activity, and this again as an indication of the age of the cell, the neutrophile leucocytes with undivided nuclei are young and immature, those with bipartite nuclei have reached adult life and possess full functional power, and that thereafter progressively increasing nuclear division indicates increasing age and diminished functional activities. These results may also be taken as in some measure supporting the views put forth by Arneth on the relationship between the age and functional power of the neutrophile leucocytes and their behavior in the various toxemic states.

6. A Case of Chronic Intestinal Obstruction Due to Tuberculous Cicatricial Constrictions of the Jejunum. S. H. Pugh.

1. **Treatment of Gunshot Wounds of Knee-Joint.**—H. M. W. Gray presents the following synopsis of his method of treatment: Excise the wound of the skin and the superficial soiled or necrotic muscle and fascia. Enlarge the wound freely if necessary. Remove foreign bodies (previously localized by *x*-rays) after possible enlargement of the wound in the synovial membrane. Flush synovial cavity with a 5 per cent. saline solution. Thoroughly remove blood clot. In very acute cases make a fresh incision. Trim the edges of the wound in a synovial membrane, and suture it if the sepsis not acute. Insert a drainage tube down to but not through the wound in the synovial membrane. Fill the rest of wound fairly firmly with a gauze dressing. Inject formalinglycerin or ether, etc., through a fresh puncture. Clean and redisinfect the surrounding skin. Apply superficial dressings and a light bandage. Immobilize the parts in a suitable splint. If this method fails, employ free arthrotomy and possibly amputation.

4. **Continuous Irrigation of Wounds.**—E. H. Willock has devised an apparatus for this purpose. This con-

sists of a staging which facilitates continuous irrigation of a wound no matter in what part of the body it may be. The staging is made as simple as possible. It consists of an oblong frame resting on four telescopic legs. Movable transverse bars, 2 inches wide, support the part of the body that needs irrigating or draining. For supporting the buttocks special bars are made. These transverse bars are provided with vertical detachable splint bars for the purpose of fixing a limb if necessary. Extension can be applied from the end of the frame. A deep tray hooks on underneath the frame and is placed wherever it is required. It is provided with a stopcock, and if the fluid discharged into it is excessive it can then be passed on by means of rubber tubing into a further receptacle under the bed. The legs rest upon fracture boards, and can be adjusted to enable the frame to be raised or lowered or tilted at an angle. The advantages claimed for the staging are: (1) Free continued irrigation can be carried on in any part of the body. (2) There is an entire avoidance of heavy dressings and "pus poultices." (3) Free drainage is secured from dependent parts.

5. **Trypanosomes.**—By Sir David Bruce. (See page 203.)

Berliner klinische Wochenschrift.

Blood of Slaughtered Animals as Food.—Salkowski refers first to the possibility of preserving blood which is strongly inclined to putrefy, especially in hot weather. We know of no chemical substances which can preserve blood which shall be edible, but the fluid can be kept from putrefaction by salicylic or boric acid. Before it can be utilized as food it must be coagulated, after eight-fold dilution, by heating; after which it should be strained through muslin. The resulting proteid coagulum is tasteless, soft and neither granulated nor sandy. It may be used in many ways for food purposes—may be stirred into soups, mixed with preserved fruits, etc. From another viewpoint blood may be mixed with cane sugar, which is hostile to putrefaction and has indeed long been known as a dressing for putrid wounds. Long before the present war the author made studies of sweetened blood from this viewpoint. The author is also much interested in "albumin bread" made from blood and naïvely states that the consumer need not know the source of the albumin. The present war bread contains 4.38 per cent. of protein, of which 60 per cent. is utilizable. If the bread ration is 221 grams daily the consumer gets 5.52 grams assimilable protein for that period. If, however, bread made with blood is used, the latter figure will be changed to 13.88 grams. This bread, first devised by J. Block is termed by the author "Block bread." Block has in fact compiled a collection of recipes in which blood albumin is an important ingredient. Dried and powdered blood has a relatively small field of usefulness by reason of its grittiness and unpleasant taste. These drawbacks, as already mentioned, are not present in the sweetened coagulum which is a semi-solid mass of the consistency of marmalade, having an agreeable taste. Its stability has not yet been determined. To prepare it an equal quantity of sugar is added to the blood and the whole evaporated. The author terms it albumin-marmalade. The best use of blood as a special food dish is the smoked blood sausage or pudding, made as a rule from pig's blood. There is no doubt that ox blood would answer equally well.

Digestibility of Mushrooms.—Loewy and von der Heide refer to the large protein constituent of mushrooms in connection with their slender nutritive value. Dried and powdered fungi are said to be more nutritious than the crude article. Most of the work done on this subject goes back about thirty years and the results obtained showed a wide range of variability in accordance with the species studied. The authors reduced to flour the so-called stone fungus, which is known to be rich in nitrogen and highly palatable. Unground fungus was used as control. Subjects were placed on a fixed diet of meat, cakes, potatoes, butter, and mushrooms and the nitrogen metabolism studied. The mushrooms contained 43 per cent. of nitrogen, and the utilization was very imperfect, perhaps on an average 50 per cent. Milling did not in the least increase this utilization. Mörner found that 33 per cent. of mushroom protein occurring in the form of chitin was indigestible, while 41 per cent. could be peptonized by pepsin and trypsin. The remaining 26 per cent. was extractive matter, chiefly amino acids. But the utilizability of mushrooms is conditioned largely by the large unabsorbable fraction. The remainder is as utilizable as fine wheat flour, but no means are available to separate the two fractions.

Syphilis and Gastric Symptoms.—Brugsch and Schneider reach some conclusions as a result of an extensive study of this subject. These are as follows: Ulcus ventriculi in a subject with tertiary syphilis usually sets in without hyperchlorhydria, the acidity being in fact diminished. Achylia is very common in lues as a probable result of chronic gastritis. Sensory irritative symptoms are present due to root neuritis in the middle dorsal segments. These have really no connection with the stomach but cause gastric symptoms and suggest tabes. Sensory gastric crises from vagus irritation may occur. Motor gastric crises occur, typical and atypical. But hypersecretory disturbances associated with pain (ulcer symptoms) cannot exclude syphilis.

Münchener medizinische Wochenschrift.

June 8, 1915.

Late Complications of Frostbites. — Burkard saw among several dozen frost bites among the Austrian troops during the Carpathian campaign last winter several cases of intercurrent phenomena of threatening character which developed in the midst of smooth healing. The material in general consisted in freezes of the third degree, in some cases extending as deep as the metatarsals. The duration upon admission had been from one to two weeks. A line of demarcation was invariably present, and in the majority of cases the gangrene was moist. The treatment consisted of deodorants, aseptic dressings, and exposure to direct sunlight, which favored mummification. The sloughs were allowed to come away of themselves. In one case at least three weeks after the exposure and ten days after admission the temperature, hitherto normal, suddenly rose to 40 C. As the wound at first showed nothing to account for this behavior, typhoid fever was suspected, but after 24 hours there appeared just outside of the line of demarcation a bright red, very sensitive areola. Realizing that a dangerous general infection was in progress amputation was performed, at first a Lisfranc disarticulation, and later a high thigh amputation, but the patient died. In a second similar case after six weeks smooth healing, local amputation checked the generalization of the sepsis. Later lymphangitis developed along the entire extremity but yielded to free incisions. A third recovered case was very much like the second. The author explains his cases as follows: Study of two of the preparations shows that the line of demarcation ran through a phalangeal articulation. The structures which enter into the formation of the joints are very resistant toward

the necrotic process, especially the cartilaginous surface. During the period of latency the joint was protected from infection, but when sloughing had progressed sufficiently the now defenceless joint was attacked by pathogenic organisms. In such cases the question of amputation at an early date must be entertained.

A Wandering Horsehair. — Guhrauer relates briefly two observations. Three years ago the author's father summoned him and pointed out to him on the sole of the left foot a small inflamed point the size of a pinhead. Beneath it one saw a small, dark splinter. The author, by means of a needle, freed the object, which proved to be a horsehair 20 cm. long. The removal was painless and bloodless. No wound was left behind. The hair was evidently from a hair mattress. The second case occurred in the author himself. After a bath, as he was putting on his right stocking, he saw above the flexor tendon of the great toe, and projecting for 4 or 5 cm., a horsehair. This was painlessly removed and measured 20 cm. in length. The wound closed at once. The author has no idea as to how or when the hair entered the foot.

Roentgen-Rays in Hay Fever. — Schmidt, himself a sufferer from this affection, having tested upon himself all the customary remedies, exposed himself, just before an expected outbreak which had already given warning of its appearance, to a one-third erythema dose (Sabouraud-Noiré). He used a small Burger therapeutic tube of about 7-8 Wehnelt hardness. After a few days evidences of irritation were absent, and the customary attack had been aborted. Since that period the author has tested the resource on a woman patient. She was much benefited by the first radiation, and after a second, fourteen days later, was practically well. The author's own disease reappeared during the summer, and while he improved under a second exposure he was disappointed in the result. The war then broke out and he could not further avail himself of the treatment.

Deutsche medizinische Wochenschrift.

June 3, 1915.

Possible Spread of Leprosy from Russia to Germany. —Blaschko refers to the recent occupation by the German Eastern army of certain Russian Baltic territory, in which leprosy is endemic. In Memel, East Prussia, is the solitary German focus of the disease, and this region abuts against the Russian government of Kowno and province of Kurland. In Livonia leprosy has existed since the Middle Ages, and although it had nearly died out, underwent a recrudescence in the Nineteenth Century. In 1904 there were probably 1,000 lepers in these localities, a notable increase during the preceding decade, but in 1910 there was another decline. There were in that year 581 lepers in Livonia and 176 in Kurland. All the lepers reported at Memel are at once interned and there has been no fear of a spread of the disease on German soil. Now it is of course different, for German troops occupy territory in which lepers abound—by no means all of whom are interned—without taking account of concealed cases. The disease is feebly but surely contagious for some individuals. Perhaps one soldier in 10,000 will contract it, but there are 300,000 German troops in the infected territory and after the war is over these will be scattered all over Germany. In regard to mode of transmission this is very likely effected by vermin. Aside from keeping the troops away from lepers, notably from houses which have been sheltering them, the only prophylaxis is one directed against vermin, consisting of the application to the clothing of naphthalin or powdered cresol.

Fitness and Unfitness for Campaign and Garrison Duty.—According to Christian fitness for active military service is a matter of health, physique, and endurance. To secure these desiderata a strict selection eliminates a large number of individuals, some of whom have trifling anomalies *per se* but such as antagonize efficiency. By a satisfactory physique is meant one which enables its possessor to walk, run, leap, climb, kneel, and lie down. A criterion of robust health is not given, beyond the statement that all functions are properly performed. After the original selection has been made the question of unfitness is bound up in the soldiers who have sustained lesions or developed disease. In as far as a *restitutio ad integrum* is concerned these men may again become eligible for active duty; but if their usefulness is impaired they may be relegated to garrison duty. As a result of injury or disease the normal endurance may suffer and this is seen especially in the undernourished, anemic, and neurasthenic subjects. Generally speaking, the chief difference between active and garrison duty lies in the fact that the latter involves neither marching nor exposure to bad weather. Also eligible for garrison duty are those originally rejected for active duty for defects trivial in themselves but which interfere with functions necessary for active duty, as crooked or stiff fingers and toes, chicken breast, scoliosis, chronic inflamed eyes, etc. Garrison duty may even be performed by those with hernia, varicose veins, hemorrhoids. In the German army there are four grades of garrison troops, depending on the relative degree of incapacity for active duty, and the same number of degrees obtains for total unfitness for military duty of any kind. Men who are actually crippled or who have no index finger or thumb, or are blind in one eye or who have any one of two score or more shortcomings which interfere even with garrison duty can be used as laborers, skilled or unskilled. These men were never eligible for military service, and their unfitness, therefore, has not been due to war injuries. They work as saddlers, cobblers, tailors, etc.

Four Cases of Ichthyosis in a Family of Six Children. —E. G. L. Goffe reports these cases. The ages of the children ranged between eight months and ten years. The condition was not present in either parent but was present in the mother's brother.—*Proceedings of the Royal Society of Medicine.*

The War and Psychiatry.—Isabel Emslie notes that the war has not made any increase in insanity as far as civilians are concerned. Among those in which insanity may be said to have been caused by the war, the great proportion of cases are those people who have had previous attacks and those who are weak-minded or very highly strung. Few normal persons seem to have been affected. Many of the admissions to the asylum show that though their psychoses were not actually caused by the war, nevertheless this was playing a large part in evolution. This factor was very noticeable in the admissions which occurred in the first month or two after the commencement of the war. It has gradually become less and less frequent, till now it is rarely seen. The mental shock of the war is apparently not so keenly felt now by the unstable mind as when the blow first fell. Of patients already suffering from psychosis when the war started, it could not be said that one had a relapse which might be traced to the war. The patients who were most affected were the paranoiacs, who, though they apparently had a normal outlook on the war, really had their own distorted views of it and had developed many and varied delusions.—*Edinburgh Medical Journal.*

Insurance Medicine.

The Appointment and Management of Local Examiners.—Dr. I. H. Florence, Medical Director of the Great Southern Life Insurance Company, Houston, Texas, read a paper on the above subject before the Medical Section, American Life Convention, French Lick Springs, Ind. He said that medical directors all recognize local examiners as their sheet anchor, but at the same time the subject is more or less of a disturbing one. The question is how to proceed to get the best service. A plan that has proven satisfactory is that blank applications for examinerships be sent out by the medical department. Agents should be instructed in case of towns where no examiner is listed, if he has an applicant for examination, to get into touch with the home office or to use his best judgment in selecting a doctor and continue his services till further instructed. When the blank is sent direct from the medical department it impresses the doctor with the fact that his appointment comes through that service and not from the agent. It is essential that the list of examiners be complete in proposed new territory before the agency force goes into the field. Hence, the medical director should be given ample time to make his appointments in any proposed new territory into which his company contemplates entering. This will eliminate some of the friction that naturally arises between the agency and medical departments.

Upon entering a new State or district a good and practical plan is to obtain lists from other companies who have been operating in that State for a number of years, and by the aid of two or three lists and the different medical directories evolve a list from the combined information.

The usual routine of sending inquiry blanks to the doctor's references is useless. Whether it is better to have a first and alternate examiner in a locality or to put them both on the same basis, is a matter of opinion and choice. After an examiner has been appointed he should be protected and favored to the extent of requiring the agents to use him when available. When an agent persists in using other than the regular appointee, especially if he does so without a good and valid reason, a never failing plan is to charge the fee to the agent. A vast amount of good can be accomplished by educating the local examiner, so to speak.

It is the experience of the writer that the very best service is given by recent graduates from reputable four-year schools; they are well equipped, anxious for work, and will give good service. While they have not the experience of the older practitioners, they give a careful and painstaking examination. As a rule, the young practitioner will give facts as he finds them. His ability to draw conclusions may not be as keen as the older man's; and, of course, being new in his locality is a drawback, as far as past history, habits of life, and surroundings of applicants are concerned, all of which are essential as having a bearing upon the rating of an applicant.

The Role of Traumatism in Disease Calling for Compensation.—In a paper read before the British Assurance Medical Society, on May 5, 1915, Sir Thomas Oliver pointed out that in the evolution of industrial legislation employers had been forced to accept responsibility for all accidents to their workmen occurring in service. By the Employers' Liability Act, liability was possible only if there had been negligence on the part of the employer, but by the Workmen's Compensation Act negligence as a contributory qualification is no longer necessary, either on the part of the employer or the workman. To-day employers are held responsible for all accidents. As legislation proceeded it became difficult to separate accident from industrial disease. Tuberculosis and traumatism is first discussed by Oliver and a case is given in which a judge awarded full compensation on the ground that the pulmonary disease from which the patient suffered was the result of an accident. In dealing with the question all the pros and cons are discussed and the verdict seemed to be that there is some relationship between traumatism and tuberculosis.

As for a casual relation between diabetes insipidus and head injury the speaker thought that in some instances this might occur and further that the strain and worry to which engine drivers, who as a class die from diabetes mellitus in larger numbers than men engaged in other occupations, are especially exposed may tend to cause the disease, and thereby afford grounds for compensation. With regard to cancer and traumatism it is likely that local injuries play an important part in the causation of the disease. Again there are traumatic neuroses.

Finally, Oliver drew attention to the fact that one notable feature of accidents to working men since the Workmen's Compensation Act came into operation is the unwillingness on the part of the injured to return early to work. There is no difference between fractured limbs to-day and fractured limbs twenty-five years ago, and yet a working man who has his arm or leg broken to-day takes as many months before he returns to work as his predecessor required weeks a quarter of a century ago. Insurance companies, in Oliver's opinion, occasionally do harm by not paying injured men promptly and by not paying a lump sum down. It is a financial question which must be settled by experience. The rate at which traumatic neuroses, according to the speaker, are increasing among female workers in all trades is a noticeable feature of modern industrial life, and for this the Workmen's Compensation Act is no doubt partly responsible.—*Medical Press and Circular*, May 12, 1915.

Some Accident Insurance Decisions.—That an insured is shot under the mistaken belief that he is another does not, it is held in Alabama case of Continental Casualty Company v. Cunningham, L. R. A. 1915 A, 538, prevent the shooting from being intentional within the meaning of an accident insurance policy reducing the recovery in case the injury results from the intentional act of insured or any other person.

Chance contact with poison ivy which results in death is held in Railway Mail Association v. Dent, L. R. A. 1915 A. 314, to be within the operation of a policy insuring against death from accident, but providing that no sum shall be due unless the accident alone results in producing visible external marks of injury or violence, nor unless the death results wholly from that injury. But it is further held that chance contact with poison ivy which results in the spread of an eruption over the body and death is not within a provision in an accident insurance policy exempting the insurer from liability where death results from poison taken or administered accidentally or otherwise.

Society Reports.

AMERICAN ASSOCIATION OF IMMUNOLOGISTS.

Second Meeting, Held in Washington, May 10, 1915.

THE PRESIDENT, DR. GERALD B. WEBB, COLORADO SPRINGS, COLO., IN THE CHAIR.

(*Concluded from page* 168)

A Study in Blood Counts in Relation to Vaccine Therapy; Autoinoculation in the Treatment of Mouth Infections.—Dr. JOSEPH HEAD of Philadelphia presented this communication. He stated that during the past year, as in previous years, vaccine had continued to prove of great value in the treatment of mouth infections, but it must not be forgotten that vaccine without effective surgical treatment could be of little service. The essayist showed charts which demonstrated the value of blood counts in the use of vaccines and said that the blood counts had taught him to be more moderate in his dosage, and he had found that patients responded at least as well as, if not better than when the doses were pushed to the point of getting marked reactions. He cited the blood counts in several cases which showed that without them injury might unquestionably have been done by excessive dosage with vaccines. Lymphocytosis did not seem to be as much of a factor as he had thought last year. When he had first undertaken the work he had hoped to be able to make more positive statements than his later knowledge would permit; this was largely due to the difficulty he had had in finding individuals with a normal leucocyte count. The essayist stated that no paper on mouth infection would be complete without some reference to amebæ. He had been using emetine, 1/3 of a grain administered hypodermically, in the arm or back for ten successive days during the treatment and had felt that it was a great adjuvant to the vaccine treatment of mouth infection. However, no single drug would cure advanced pyorrhea alveolaris without the aid of good dental surgery. The most successful remedy, usually an actual specific, for pyorrhea was autoinoculation by means of the energetic use of a stiff tooth brush and floss silk. The speaker then described his method of removing the offending matter of microorganisms and at the same time securing a curative autoinoculation by the use of these mechanical cleansers. Improperly used, or used as it was ordinarily, Dr. Head said, tooth brushing was a delusion, but scientific, careful cleansing with implements of the proper size and shape would unquestionably add years of healthful existence to every man, woman, and child in the community at large.

Dr. C. C. BASS, Tulane University, New Orleans, La., said that the subject of pyorrhea alveolaris had interested him many months and the more he studied the subject the deeper he got. He was now studying the pathology of the disease but later he expected to take up the bacteriology and then the protozoology, and finally the treatment of this disease. The information he had got during the past few months was appalling in showing the great prevalence of the disease. It had taken a great deal of time before they were able to make the diagnosis, but he still found that in many cases it was still impossible to make a correct diagnosis. The diagnosis made by the dentists was no better than the diagnosis he made. As they all knew, the dentist made the diagnosis of pyorrhea alveolaris when he was able to squeeze pus from the gum or a pocket around a tooth. Whenever he saw a drop of pus, he made the diagnosis of pyorrhea. The condition could not be cured by simply giving medicine. The surgical treatment was what was called for. They had seen about 500 cases and found only two of this number in whom they were not able to demonstrate pus and the *Endameba buccalis*. The endameba did not attack normal tissues; there must first be present damaged tissue, some particular tissue that was susceptible to infection. It should be remembered that the *Endameba buccalis* lived, grew, and reproduced in the peridental membrane of the human being, and probably that of other animals. It fed upon certain cells that were found in some suppurative foci. The kind of cells it fed upon were much more numerous in suppurations next to bone tissue. The endamebæ were continually crawling around and hunting for food, ad were in direct communication with the bacterial flora contained in the mouth. Dr. Bass did not believe in any treatment that did not take into consideration the rôle played by the *Endameba buccalis*. The surgical treatment was very important. The lesions progressed rapidly with destruction of the soft parts, thus exposing the bone. The danger from this disease came from the members of the family who drank from their cups leaving the *Endameba buccalis* where an acquired lesion would be infected, a mouth to mouth infection. Everybody, if he lived long enough, would lose his teeth from this disease if untreated; it was a long sloughing process and dependent upon the flora in the individual mouth.

Further Experiments in the Production of Immunity to Tuberculosis.—Drs. GERALD B. WEBB and GEORGE BURTON GILBERT of Colorado Springs, Colo., presented this communication. They recalled that they had previously shown that a thick emulsion of blood platelets added to a lethal dose of tubercle bacilli appeared to modify the course of the infection or to prevent it. However, this did not furnish a practical, safe, and reliable method of inoculating living virulent bacilli for purposes of immunization. It had seemed desirable, in view of the importance attached to the rôle of the lymphocyte in nature's battle against tuberculosis, to determine whether an emulsion of lymphocytes added to a lethal dose of tubercle bacilli could influence or prevent infection. Lymphocytes were obtained by injecting four c.c. of sterile Binger's solution into the peritoneal cavity of guinea pigs and about ten minutes later withdrawing some of the fluid by means of capillary pipettes and immediately mixing with a definite number of bacilli obtained in a capillary pipette by means of the Barber method. After incubating for twenty minutes this mixture was inoculated subcutaneously in the nipple area of adult guinea pigs. Samples of the fluid obtained from the injected guinea pigs, when stained, showed a practically pure emulsion of lymphocytes, at least 95 per cent. at the time chosen as most favorable. Both normal and tuberculous guinea pigs were used for obtaining the leucocytes in different experiments without appreciable difference in the results. The formation of a fibrin network which collected the lymphocytes and permitted only a perfectly clear fluid to be withdrawn from the pipettes was overcome by having the doses of living bacilli already picked out in separate pipettes so that they would be mixed with the lymphocytes at once. In one experiment, serum, both heated to 56° C. and unheated, from both normal and tuberculous guinea pigs, was added to the lymphocyte bacilli mixture and the whole incubated before inoculation. In this series of five experiments no uniform and constant action by the lymphocyte emulsion so far as actually preventing infection could be detected. Indeed any uniform modification of the course of the disease also seemed to be lacking. The tabulated data of these experiments was presented and also the autopsy results.

Concerning the Occurrence of Tubercle Bacilli in the Circulating Blood.—DR. LOUIS HAMMAN of Baltimore read this paper. He commented upon the unsatisfactory state of their information concerning the occurrence of tubercle bacilli in the circulating blood. The literature upon the subject was full of the grossest contradiction. Some authors claimed that they found the bacillemia in all cases of tuberculosis, others that they discovered tubercle bacilli in the blood only in the last stages of the disease; still others contended that they found them even in the last stages of the disease only exceptionally. The results of microscopical examinations of the blood were unreliable, since there were so many possible sources of error; but even by animal experimentation some authors reported a very large number of positive results; some, indeed, as high as 50 per cent. of the cases examined. The speaker's investigation of this question upon patients in advanced stages of pulmonary tuberculosis and in animals inoculated intravenously, led him to draw the following conclusions: Tubercle bacilli occurred in the blood in sufficient number to be demonstrated by animal experiment only in the last stages of pulmonary tuberculosis in human beings, and then only infrequently. In animals they were constantly found when a very large number of organisms was injected intravenously. When smaller numbers were injected, and the disease remained localized relatively to the lungs, no bacillemia occurred until toward the end of the investigation, when the disease became general.

Dr. GERALD B. WEBB of Colorado Springs, Colo., said that it was puzzling to men who were working in tuberculosis to know how to interpret the various results they obtained regarding the occurrence of the tubercle bacilli in the circulating blood. Anyone who studied

the growth of the tubercle bacilli in the incubator realized what a sticky mass there was to deal with. The typhoid bacilli, as they all knew, made no such a sticky emulsion, but with the tubercle bacilli it was different. In their work in inoculating this bacillus it was extremely difficult to do the work because of this stickiness. In these cases of bacillemia the tubercle bacilli were said to be frequently found in the circulating blood. The clinicians must realize that they did get in. They must get there through the circulating blood stream and settle in certain regions. Dr. Webb asked Dr. Hamman what he knew regarding the type of the tubercle bacilli described by Landouzy—the typhoid type of bacilli.

The Virulence of Various Strains of Human Tubercle Bacilli. — Drs. GEORGE BURTON GILBERT and HAROLD GREGG of Colorado Springs, Colo., presented this preliminary report. They said that the use of live bacilli for the production of immunity had been of little avail because of their inability to control the exact numbers and the virulence of the bacilli. The ingenious device of Prof. M. A. Barber made it possible to isolate and inoculate any given number of living virulent tubercle bacilli. Using this same method it has been possible to show great variation in the minimum lethal dose of different virulent cultures. The authors presented a list of certain cultures and the smallest number so far found capable of producing progressive and fatul tuberculosis in adult guinea pigs. In an effort to obtain a culture of moderate virulence for future work along immunological lines it was decided to obtain a large series of cultures of tubercle bacilli from different types of cases and from different organs of the body and then to study these in detail as to virulence. The cultures were obtained using the media recently advocated by Petroff, consisting of 1/10,000 gentian violet, two parts of whole egg and one part meat juice. Definite numbers taken from the fresh cultures less than one month old were inoculated subcutaneously in the nipple area of adult guinea pigs. Both local and internal lesions were studied. Owing to the lack of guinea pigs only six cultures could be reported on at the present time. The tabulated results with the various cultures showed the absence of both local lesions and local regional glands in seven instances where macroscopic disease was found in one or more internal organs. This was quite unusual in their experience. It was certainly safe to assert that great differences in virulence occurred in virulent cultures obtained from various cases. Whether cultures obtained from varied organs varied regularly in virulence remained to be determined.

The Direct Treatment of Cerebrospinal Syphilis According to the Method of Swift and Ellis.—Drs. CLYDE L. CUMMER and RICHARD DEXTER of Cleveland, after outlining quite fully the work of Swift and Ellis in the treatment of syphilitic diseases of the central nervous system, and reviewing a number of the reports of others who had employed this technique, concluded that from this work one gained the impression that the definite changes could be brought about in cases of paresis, but that the permanence of the improvement was still open to question. There was no doubt that many cases of tabes and cerebrospinal syphilis had been markedly improved symptomatically and that the laboratory findings in certain cases had returned to normal. Practically no changes had been recorded in the deep reflexes or the pupillary responses in tabetics. Certain criticisms of this method had been made, one being its danger. A careful search of the literature showed that the reported deaths had been among paretics, and no fatalities had occurred after the treatment of tabetics. The number of fatalities in the total number of treatments was not alarming, considering the desperate outlook in this condition. Another criticism was that arsenic had access to the spinal fluid when present in the blood stream, and therefore its direct introduction into the subarachnoid space was needless. This point was at least open to argument, since Camp stated that he was unable to discover arsenic in the subarachnoid fluid after salvarsan had been administered intravenously. The main question was whether this method of treatment was productive of symptomatic and functional improvement as well as the indubitable improvement in laboratory findings. It was to aid in answering this question that this series of cases was reported. While the number of cases was limited, the value of the report was enhanced by the length of time through which they had been able to continue their observations. In addition to two preliminary cases that were under their care for so short a time that they could not be considered, they had treated eight patients suffering from definite tabes or syphilitic meningo-endarteritis. They had followed rigidly the Swift-Ellis technique which they outlined. Their cases were divided into three classes accordingly as they showed decided clinical improvement, moderate or slight clinical improvement, or had been under observation so short a time that it was unfair to draw conclusions. The cases were all reported in detail and carefully tabulated records of the laboratory findings were presented. The first patient, a man of twenty-nine years, having cerebrospinal syphilis, had been under observation for over two years. During this time he had received twelve intravenous injections of salvarsan or neosalvarsan (the total being equivalent to 5.4 grams of salvarsan), and seven injections of serum intraspinously. In addition to this much mercury had been given in the form of intramuscular injections and inunctions. He now reported that he had had only one attack of pain during the past year. The second case was one of moderately advanced case of tabes dorsalis in a man forty-five years of age, in whom serologically there was marked improvement. The neurological physical examination showed absolutely no change except a restoration of sensory perception. From a functional and symptomatic standpoint this patient was vastly improved. The third case was also one of moderately advanced tabes dorsalis who had been under observation for eleven months and clinically his case was one of great betterment. The pains had disappeared except for recrudescence in a mild form when fatigued. Physical examination showed no change in pupils or reflexes, but the Romberg sign was less marked and the muscle sense was improved. The laboratory findings were the most gratifying in the entire series. In the fourth case, one of early tabes in a woman of thirty-four years of age, the improvement after the institution of intravenous and intraspinous treatment was rapid and striking. The laboratory findings were most satisfactory while the clinical result was the most striking in the series. The pupillary reaction and the ankle and knee jerks were unchanged. The fifth case was one of moderately advanced tabes in a man of thirty-nine years. The clinical results in this case were a restoration to economic efficiency, a marked gain in weight, and the removal of certain unpleasant symptoms due to the marked sensory changes which occurred early in the condition. The laboratory findings in this instance were greatly improved. Of the class showing moderate or slight improvement one of advanced and one of moderately advanced tabes, the latter was notable in the entire disappearance of the Wassermann reaction. The spinal fluid of the advanced case showed no improvement over the first barring the reduction in the cell count. After reviewing the histories of the cases that had been under treatment too short a time to enable one to draw any conclusions, they summarized their work as follows: They had given forty-eight intraspinous injections of serum and seven treatments of a similar nature not reported in detail, making a total of fifty-five.

They had had no untoward or unfortunate results in any instance. With all the patients but two sharp reactions had occurred following the intraspinous injections. When any form of crisis or lancinating pain had been present the reaction had usually taken the form of an exacerbation of this symptom. The greatest improvement had usually followed the severest reactions. With reference to changes in the laboratory findings, study of the tables showed that lymphocytosis disappeared quite promptly, after one, two, or three injections. The globulin test was usually slower to disappear. In their experience the Wassermann reaction was the most obdurate of the laboratory findings. Practically the only changes in the physical condition which they had been able to detect had been restoration of sensation, when this had been impaired, disappearance of Romberg's sign, increase in muscular strength, and a diminution in ataxia. In no instance had they noted pupillary reactions return to normal, nor had absent deep reflexes reappeared. The greatest improvement had been obtained in symptoms. Lancinating pains had disappeared entirely or were greatly diminished, and in one instance gastric crises had disappeared. The striking feature was the improvement in general condition, in weight, strength, and well being. In conclusion they felt that they could state fairly that the Swift-Ellis method was safe when the original technique was followed painstakingly. Persistence was necessary to obtain the best results. This treatment was a valuable adjuvant in the treatment of syphilitic diseases of the central nervous system; claims of the originators were

sustained as far as tabes and central nervous system syphilis was concerned. It was a method which was not necessary in all cases, but applied carefully and controlled intelligently it would bring about a definite amelioration in laboratory signs and in symptoms where the accepted form of treatment had failed.

Dr. WILLIAM E. ROBERTSON of Philadelphia said he had reached the same conclusions as the authors with respect to the amounts of spinal fluid to be used in making the Wassermann test. In his earlier work he stated that 0.4, 0.6, and 0.8 were routinely employed, but a series of observations led him to the conclusion that larger amounts were necessary, and for two years he had used routinely three tubes containing 0.5 c.c. and 1 c.c. and 1.5 c.c. respectively. Occasionally only the largest amount would yield a positive result, the others being negative. In paresis, however, it was the rule to find all three tubes positive. In every instance he not only made a Wassermann on the spinal fluid but counted the cells, did a Nonne, Noguchi, Fehling's, and gold solution test. With regard to the count he referred to the very interesting work of Dr. Weston of the Warren State Hospital, Pennsylvania, who made a very large number of counts and found that they varied day by day and without any apparent reason. So striking was this that Dr. Weston was led to the conclusion that counting the cells was of no practical value. In all instances Dr. Weston's counts were made within a few minutes of taking the spinal fluid so that no opportunity for cytolysis was given. Dr. Robertson said that he had had no opportunity to make such daily studies of the cell counts, but in his experience there was always a direct relationship between the degree of pleocytosis and the protein content of the spinal fluid. As to the gold solution he said that though the preparation of the solution was extremely difficult, the application of the test was very simple and the results of considerable value.

Dr. GEORGE P. SANBORN of Boston, Mass., said they had made 200 observations. In paresis they had obtained from the analysis of the cerebrospinal fluid just what had been obtained at the Johns Hopkins Hospital in Baltimore in tabes. In tabes they had never gotten tubes that were absolutely decolorized. In the suspected cases which gave the clinical signs of tabes and those alone, the tubes were decolorized in the first three or four days; but in these cases the nerve infection was more extensive than the clinical diagnosis suggested. In other words there might have been a paretic element in the case. They had also found that after the injection of the salvarsanized serum in a number of cases the intensity of the gold chloride reaction diminished with successive treatments. In some instances from three to four days. He had never seen a case of tabes in which they could get any definite decolorization in one tube and an ordinary growth in the rest of the tubes.

Dr. RICHARD DEXTER of Cleveland, Ohio, said that the use of small doses was an admirable titration in the treatment and one could see the reaction diminish under such a treatment. It was well to continue the treatment with small amounts made of a definite titration. With regard to the so-called typical curves occurring in tabes, in Germany and in America, as well as other countries, there had been described the typical curve of tabes. Take ten tubes; find the highest in one, the first, and the lowest in the last. The typical curve in tabes should show decolorization in the tube with certain reagents. They had been able to get the typical curves. So far as his work was concerned he could not get the swing he looked for. However they found positive reactions in a great number of cases of syphilis of the nervous system. This all showed that this took a part that was necessary in the laboratory examination of the spinal fluid from now on.

The Blind Dental Abscess.—Dr. HENRY L. ULRICH of Minneapolis read this paper, which he prefaced by stating that blind dental abscess was rather a loose term though the other names thus far suggested such as alveolar abscess, peridental abscess, or apical abscess, were not very satisfactory. Apical abscesses were never found at the roots of vital teeth. The pathological anatomy of these areas was not very well understood. The skiagraph indicated a range from a rarifying infiltration to a well-defined area of bony necrosis. Extraction of these teeth showed root necrosis and absorption. Microscopic section of these so-called pus sacs showed an outer dense area of connective tissue with infiltrating areas of round cells made up of plasma cells and lymphocytes. Various stages of acute and chronic inflammatory processes were shown. Besides round-celled infiltration polymorphic types were noted. Sections stained for bacteria proved unsuccessful. At the University of Minnesota Hospital, in an effort to correlate oral sepsis with systemic lesions, a special inspection of mouths was made for pyorrhea, gingivitis, caries, and, by means of the *x*-ray, for apical abscesses. They were struck by the frequency of apical abscesses in these cases. Further search was made for these lesions by studying the roentgenograms of the mouth in a medical *x*-ray laboratory. The findings were startling. A little over 68 per cent. of all artificially devitalized teeth were found with apical abscesses and a total number of abscesses, including those found in pulpless teeth due to caries, or death from accident, or too proximal fillings, was 83 per cent. In the examination of 500 cases, 1350 dead teeth were found and of these 976 had root canal fillings. Of these cases 159 with apical abscess had had bacteriological review and of 107 cases from the University Clinic 100 gave a streptococcus viridans. Fifty-two were from the author's private clinic and fifty of these gave a viridans or a hemolyticus; occasionally mucosa was recovered. Thus 150 of these 500 cases gave evidence of streptococcus, either in pure culture or as the dominant organism. Occasionally the staphylococcus aureus, or albus, or the micrococcus catarrhalis was also observed in conjunction with the streptococcus. To the writer the apical abscess was merely another evidence of a focus of streptococcal focal disease, just as the heart, the mucosa of the stomach, the articulations or the kidneys were evidence of secondary deposits. In other words it was hematogenous in origin. The pathogenicity of these abscesses and their relation to other concurrent foci had had ample clinical verification: First, because acute exacerbation of systemic symptoms followed their removal, that was, focal reactions occurred due to autoinoculation at the time of their reduction. Second, acute new systemic symptoms had followed reduction of these areas; in other words, other foci had been established. Third, improvement and sometimes total recession of other focal areas followed the extirpation of these sites. Fourth, local and focal reactions occurred with vaccines prepared from apical areas. A recent analysis of seventy-six cases in which a streptococcus was isolated from apical pockets showed that thirty-eight cases belonged to the rheumatoid group; six cases to the cardiovascular group; three to the asthenic; four to the gastrointestinal; two to the genitourinary allied to the rheumatoid group. A subgroup of eight cases consisted of those in whom the streptococcus focal infection was superimposed of syphilis, tuberculosis, primary anemia, or vice versa. The striking feature of this analysis was the diversity of clinical manifestations for which streptococcal focal infection was responsible. The diversity of symptoms was so marked that he had suggested the term "Streptococcicosis" for streptococcal focal disease. Experience with alveolar infection in which systemic symptoms were present had made them very cautious concerning the apparently innocent looking tonsil. Invariably the same tonsil on closer inspection, and particularly after it had been removed under protest, had proven their suspicions correct. To those who were attempting active immunization to disease, the blind dental abscess had a very practical significance; it might be the only focus left and might hold the balance of power in the struggle of the body for complete sterilization. In every case of streptococcal focal infection its presence or absence must be established. Such a focus would furnish material for the preparation of vaccines and much trouble and disappointment from attempting cultures from glands and tonsils could thus be avoided. Of the more striking symptoms in these groups they had manifestations of rheumatoid conditions in 51 per cent.; heart lesions, 47 per cent.; secondary anemia, 43 per cent.; tonsils, 40 per cent.; pyorrhea, 25 per cent.; kidneys (albuminuria and nephritis), 34 per cent.; caries, 15.8 per cent.

Dr. GEORGE P. SANBORN of Boston, Mass., said that in cases of rheumatism or joint infections it was up to them to find some local infection which was the cause of the trouble. Eliminate that cause and good results would follow. There were so many cases, however, where it was impossible from the clinical history to tell where the local infection was. In such cases the use of the *x*-ray was of great value in seeking for the local infection, or the foci in the mouth. He also wished to emphasize the importance of having a man examine the

throats, a man who was one up to date and experienced in this work. He reported an interesting case of a chauffeur who every two or three months, after being exposed to cold while driving the automobile, suffered with chills, high fever, which after a short time disappeared. In looking carefully in the throat nothing could be noted which might be attributed as a cause of his disturbance. A casual examination of the tonsils was made but with the use of the tongue depressor pus was expressed from the tonsil. He had had no evident trouble with his tonsils; they had never been even sore. A tonsillectomy was performed and he then was relieved of his rheumatic affection and was entirely cured of his attacks which caused him so much annoyance. It was interesting to note that there might be these foci of infection and yet no clinical symptoms were evident.

Dr. Judson Daland of Philadelphia said he wished to speak regarding the occurrence of a tonsillar infection without any clinical evidences of such a condition being present. He thought that many of them had met with many such cases and where the pus foci were deep in the tissues. In many cases even after the tonsils were removed the symptoms would persist and, after careful search, there would be found a post-tonsillar abscess which they had not been able to diagnose. There seemed to be an extraordinarily large number of such cases.

Dr. Joseph Head of Philadelphia recalled a case in which the condition of the tonsils appeared to be all right; the tonsils however were removed and the joint affection persisted. It then occurred to him that the use of the *x*-ray might have revealed some foci of pus around the roots of the teeth which accounted for the symptoms complained of—certain depots of pus around the roots. Was it the tonsil that caused the trouble? He did not wish to have them think that he in any way discredited the value of the paper just read.

Dr. Claud P. Brown of Glenolden, Pa., said that in doing tonsillectomies there had been no tonsils completely removed but that they found myriads of bacteria and many of them of a pathogenic nature. After searing the cut parts, inoculations were done and other measures carried out, and then they started to inject guinea pigs with 2 c.c. emulsion; every guinea pig so injected was killed. This seemed to prove that the tonsils were undoubtedly the habitat of bacterial flora, even when the tonsils appeared to be in a normal condition.

Dr. A. Parker Hitchens said he wished to relate a personal experience. He suffered from pyorrhea alveolaris while in this neighborhood and once in a while there would occur an acute "blow up." He also had a severe tonsillitis which he had treated with nitrate of silver, sprays, and so forth. The interesting thing was that the tonsillitis always came alone with the acute exacerbation of the pyorrhea alveolaris. Since the pyorrhea had been cured by the extraction of certain teeth he had not since been troubled with tonsillitis.

Dr. Gerald B. Webb of Colorado Springs, Colo., asked Dr. Ulrich if the use of the *x*-ray would enable them to make a diagnosis of the apical portion of the teeth when there was a pus focus present. Would not the *x*-ray fail to show such a focus of infection?

Dr. Henry L. Ulrich of Minneapolis, Minn., closed the discussion. He showed some pictures which were quite characteristic. With regard to the *x*-ray interpretation, this was a matter about which they were still at sea; they did not care to extract teeth to find out the cause of trouble, but when they had done so they had found bacteria. As a matter of fact, after extracting teeth because of abscess formation, and when they made sections, they did not find necrosis but the results of ordinary inflammatory conditions. Histologically they had not yet worked out the study to their satisfaction. There was nothing to be found in the literature. There was merely a round cell infiltration present. What was of particular interest to him was that these abscesses were found so frequently and he believed that they must be secondary abscesses and not any primary foci or infection. With regard to the relief of tonsillitis after the extraction of teeth, that was readily explained by the vaccine theory.

Therapeutic Inoculation in a General Hospital; Personal Experience Covering Seven Years.—Dr. George P. Sanborn of Boston presented this paper. He declared that among the most important problems of the present day in connection with specific treatment of infectious disease in general hospitals was the development of an organization to carry on this important work. That these cases could be treated at present successfully, efficiently, and economically in the various departments in which they occurred was out of the question. The writer said that since his return from the Wright Clinic in 1908 he had made it his chief work to organize a department in the Boston City Hospital, which should receive from the various already organized departments suitable cases for active immunization, in order that they might be grouped and thus receive the careful treatment they deserved. It was felt that present and future developments in the specific treatment of infectious disease would yield a sufficiency of interest and required a sufficient amount of specific detail laboratory and clinical work to engage the exclusive attention of one department designated for the purpose. At the start in 1908 the activities of this department were limited largely to the out-patient clinic, with the idea of furnishing the greatest good to the greatest number. In connection with the work of others in the same direction it had been the writer's hope to bring forward sufficient volume of scientific data as to the methods of treatment and as to end results to make possible a more definite standardization of method of vaccine therapy and a more general acceptance of its efficacy in the treatment of some of the acute, but chiefly the subacute and chronic localized infections. The paper was not intended as an analysis of the cases treated, but to show the amount, character, and scope of the work which was being done with the above end in view. The work of the department included curative vaccine inoculations, prophylactic inoculations against typhoid, salvarsan chemotherapy, and later chemoserum therapy for nerve syphilis. The following data summarized the routine work of the past two years. During this time curative vaccine inoculation had been practised in 994 cases. These patients visited the clinic 6,697 times and had received 5,880 bacterial vaccine inoculations. As a basis for their treatment more than 650 cultures had been examined and over 600 vaccines had been prepared. The type and number of cases treated were as follows: Acne, 161 cases; furunculosis, 369 cases; carbuncle, 39 cases; gonorrheal arthritis, 101 cases; tuberculous adenitis, 162 cases; other cases of local tuberculosis, 37 cases; superficial pyogenic infection, 49 cases. These conditions had furnished about 75 per cent. of all the cases treated. Excepting in tuberculosis and gonorrheal arthritis, it had been the rule to prepare autogenous vaccines for every patient in which proper cultures could be obtained, and this had added greatly to the amount of laboratory work. The results had justified the extra labor. It had been possible to shorten the course of treatment compared to that of 1912 in at least 70 per cent. of all cases, the average number of visits per person having dropped from 10.8 visits in 1912 to 6.7 in 1913 and 1914. It was believed that the regular attendance at the clinic showed the satisfaction of the patients with the treatment and the results. Antityphoid inoculation had been applied since June, 1911, to a total of 535 individuals, mostly nurses. Since the introduction of the antityphoid inoculation no nurse had developed typhoid fever in the hospital though there had been two cases developed more than two years after protective inoculation had been given. It was their custom to repeat the inoculation after two years. In the division of chemotherapy 327 cases of syphilis had been treated. These had visited the clinic 3,589 times and had received 954 doses of salvarsan and 608 intramuscular injections of salicylate of mercury. There had been 866 blood specimens taken for Wassermann test, 57 lumbar punctures made for diagnostic purposes, and numerous salvarsan injections were given also for diagnosis. The laboratory work had involved the preparation of 954 doses of salvarsan and the solutions necessary for their preparation, and the examination of 57 spinal fluids to determine the question of syphilitic involvement of the nervous system. The cases of syphilis had been mostly in the tertiary stage, in which the requirements were elaborate and had been thoroughly met. The most important aspect of this work had been the early detection of nerve syphilis. Unless intravenous salvarsan of itself might prove to be efficient in the prevention of nerve syphilis, it was reasonable to suppose that in the natural course of events as large if not a larger percentage of cases would be candidates for nerve syphilis unless further preventive measures were applied. This has led to a systematic study of all cases of tertiary syphilis with the possibility of nerve syphilis in mind. It had been the rule to perform lumbar puncture at the beginning of treatment, if consent could be obtained, in order that the spinal fluid could be tested for syphilitic

abnormalities. These patients had also been referred to the nerve department for detection of the earliest nerve symptoms. Through the cooperation of the *x*-ray department study was being carried on in regard to the involvement of bones and great vessels in tertiary syphilis. In the treatment of primary and secondary syphilis no reliance had been placed on a single dose of salvarsan; the results of following this principle had been most satisfactory. There had been no deaths and no untoward happenings due to the administration of salvarsan. In the treatment of tertiary syphilis in the presence of nerve involvement, the experience of the writer corroborated that of Swift and Ellis and others, in showing this method to be efficient in producing clinical improvement in eliminating in varying degree conditions in the spinal fluid pathognomonic of syphilis. During the past two years the author had treated 150 cases of nerve syphilis to whom had been given 870 injections of salvarsanized serum according to the method of Swift and Ellis. In the hospital clinic 81 cases had been given 348 injections. In summing up Dr. Sanborn emphasized the advantage of this laboratory whose final interest was specific therapy and the advantages of the interrelation of clinic and laboratory and recommended the installment of such a department in all large general hospitals.

An Analysis of the Value of Laboratory Methods Used in the Examinations of Cerebrospinal Fluid.—Drs. Richard Dexter and Clyde L. Cummer of Cleveland presented this paper. They stated that they had examined a number of spinal fluids by means of the Wassermann reaction, cell count, globulin reaction, and, more recently, by the Lange colloidal gold reaction. During the past year and one-half they had been using even larger amounts of spinal fluid in doing the Wassermann reaction than had been used by Swift and Ellis. They had followed the technique described by Walker and Swift using increasing amounts of spinal fluids 0.1, 0.2, 0.3, 0.4, 0.5, and 1 c.c. In a series of 177 spinal fluids from cases with indubitable signs of lues of the central nervous system in which these various amounts were used it was evident that by using 1 c.c. of spinal fluid as a maximum amount a positive Wassermann reaction was obtained in 21.4 per cent. more fluids from known luetics than when only 0.5 c.c. was used as a maximum. A comparison of the positive Wassermann reactions in the spinal fluids with their cellular content and globulin was of interest. Out of sixty-three cases in which the cell count and globulin was done and in which the Wassermann reaction was positive with amounts of 0.5 c.c. of spinal fluid or less, they found that both cell count and globulin were increased in 69 per cent.; the cell count alone was increased in 1.5 per cent.; globulin alone was increased in 14.3 per cent. Neither cell count nor globulin was increased in 14.3 per cent. On the other hand out of eighteen fluids showing a positive Wassermann reaction in 1.0 c.c. only, they found that both cell count and globulin were increased in 16.5 per cent.; cell count alone was increased in 11.1 per cent., and globulin alone was increased in 16.5 per cent. Neither cell count nor globulin was increased in 55.5 per cent. It was apparent therefore that when the Wassermann reaction was positive in 0.5 c.c. of the spinal fluid or below, the greater were the chances that there would be an accompanying increase in the cell count and globulin content. Whereas, in those fluids which showed only a positive reaction in amounts above 0.5 c.c. one was less likely to find an increase in the cellular elements or the amount of globulin. The importance of this from a diagnostic standpoint was obvious. The question as to whether non-specific binding might not occur when such large amounts of spinal fluid were used would naturally arise and they felt that the answer to this question might be found in the following observations. Out of a total of 132 spinal fluids where lues was either non-existent or non-active, they found only one which reacted positively to the Wassermann reaction when the maximum dose of ten times the lowest dose of spinal fluid was used and this was by no means a strong reaction, as against 131 which were negative under the same conditions. After describing Lange's colloidal gold reaction and his findings, the essayists stated that it was their experience that the curves described by Lange occurred with considerable regularity. They had followed the technique laid down by Lange in his original article. In summing up the results of this investigation of forty-eight cases of syphilis involving the nervous system, they had found the cell count increased in 33 or 68.7 per cent. The globulin content was increased in 32 or 66.6 per cent., which paralleled the cell count very closely. The Wassermann reaction was positive in 34, or 70.8 per cent. of these forty-eight spinal fluids, while they found either strong or weak positive colloidal gold reactions in 77.1 per cent. of the cases. It was probable that the high percentage of positive Wassermann reactions obtained in this series was due to the fact that 1.0 c.c. of spinal fluid, ten times the Wassermann test dose, was used as the maximum amount. In spinal fluids from twenty-three cases without any sign of syphilis they had found twenty-one negative colloidal gold tests and two very weakly positive reactions. In three cases of tuberculous meningitis from which they had examined the spinal fluid they had not seen the typical curve described by Lange and others.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

State Board of Medical Examiners of Georgia.

Atlanta, October, 1914.

(*Concluded from page* 130.)

SURGERY.

1. What is surgical shock, and how treated? What is differential diagnosis between coma from injury, cerebral apoplexy, uremia, opium poisoning, and alcoholic intoxication?

2. What is a fracture? What is dislocation? Differentiate between fracture and dislocation. What are the cardinal principles in treatment of fracture? Describe Kocher's method of reducing dislocation of shoulder joint.

3. What is understood by amputation of contiguity and continuity of limb? What conditions demand amputation?

4. Give approved classification of burns. Give briefly local and constitutional treatment of burns. Is opium contraindicated? If so, why?

5. Differentiate between scrotal hernia and hydrocele. What is hernia? Give briefly approved operation for radical cure of oblique inguinal hernia.

6. Name briefly most common varieties of fistula. Describe briefly operation for fistula in ano.

7. What is understood by congestion? Inflammation? Give differential diagnosis between abscess and aneurism, and treatment of each.

8. Describe an operation for empyema.

HYGIENE.

1. What is meant by temperament, idiosyncrasy, and diathesis?

2. What is a virus?

3. What are the parasitic diseases that may be caused by eating insufficiently cooked meats?

4. Describe proper ventilation of a room of a pneumonic patient.

5. How long does a diphtheritic patient remain infective after local symptoms cease?

6. How would you instruct a nurse attending a case of diphtheria?

7. What is a disinfectant?

8. How would you disinfect rooms after occupancy by a typhoid and a tubercular patient?

9. Name the diseases, the prevention of which would lengthen the average of human life.

10. What is bubonic plague and how would you handle a case to prevent spreading?

ANSWERS.

SURGERY.

1. *Shock* is the name given to a sudden and general depression of the vital powers, due to some strong stimulation (such as injury or emotion), acting on the vital centers in the medulla and producing vasomotor paralysis. Shock is *primary* when the symptoms appear promptly; it is *secondary* when the symptoms don't appear for several hours (often observed after railway accidents, intoxication, etc.). *Treatment of shock:* Place the patient in the recumbent position, with the head low, apply warmth to the body, administer a stimulant, and give a hot saline infusion; morphine, hypodermically, may be necessary for the relief of pain. Adrenalin and pituitrin have been used with benefit. It is often very

difficult to differentiate shock from hemorrhage; but as a rule, in shock the symptoms are at their worst immediately after the injury, and tend to improve with time; and the nervous symptoms are more prominent from the first (dilated pupils, unconsciousness, etc.).

The following table (from Eisendrath's "Surgical Diagnosis") gives the diagnosis:

COMA FROM INTRACRANIAL INJURY.	APOPLECTIC COMA.	UREMIC COMA.	ALCOHOLIC COMA.	OPIUM POISONING.
Deep coma; may have history of onset after fall or injury. Evidence of fracture of vertex or base.	Deep coma; sudden onset. If any injury, only a scalp wound.	Deep coma. Slow onset unless convulsions have preceded the coma.	Can be aroused by supraorbital pressure unless very profound.	Can be aroused unless very deep.
Pupil dilated on side of lesion. Choked disc.	Pupils unequal or dilated. Contracted in hemorrhage into the pons.	Albuminuric retinitis.	Pupils normal or somewhat dilated.	Pupils contracted to pinpoint size.
Pulse very slow.	Pulse full and slow, often arteriosclerotic high-tension pulse.	Pulse rapid.	Pulse more rapid than normal and full.	Pulse rapid, may be irregular.
Respiration slow and stertorous.	Respiration slow and irregular.	Respiration frequent and irregular.	Regular respiration.	Respiration very slow —may be 6 to 8 per minute.
Temperature higher—101°.	Temperature higher on paralyzed side, but lower in rectum.		May be low or normal.	
Urine normal or contains trace of albumin.	Urine contains trace of albumin, but may be same as in uremia.	Urine shows albumin, casts, and low urea percentage.	Normal.	Normal.
Hemiplegia on opposite side to that of injury. If contusion of brain is also present, may have generalized convulsions.	Hemiplegia with convulsions on one side.			

2. *Fracture* is a solution in the continuity of a bone, caused by violence.

Dislocation is more or less sudden and persistent separation of two articular surfaces.

FRACTURE	DISLOCATION.
1. Crepitus may be present.	1. Crepitus never present.
2. Preternatural mobility.	2. Rigidity rathen than mobility.
3. Easily reduced—but	3. Difficult to reduce—but
4. Deformity more liable to recur after reduction.	4. Deformity less liable to recur after reduction.
5. The head of the bone is in its proper place.	5. The head of the bone is not in its proper place.
6. The socket containing the head of the bone is not empty.	6. The socket which should contain the head of the bone is empty.
7. When rotated the bone does not move as one piece.	7. When rotated the bone moves as one piece.

The *cardinal principles in the treatment of fractures* are: Reduction, coaptation, immobilization, and suitable measures for promoting the nutrition of the part and for preventing adhesions in the neighboring joints and muscles. Compound fractures, in addition, demand: Asepsis, removal of foreign matter or damaged tissues, stopping the hemorrhage, and measures to combat shock.

Kocher's method of reduction is: to flex the forearm, press the elbow to the side, rotate the arm outward. Bring the arm forward and upward to a right angle with the body, then rotate inward, while the elbow is brought down over the body so that the fingers sweep the opposite shoulder.

3. *Amputation in contiguity* is amputation at a joint. *Amputation in continuity* is amputation elsewhere than at a joint.

Conditions which justify amputation of a limb are: "Any injury, disease, or malformation rendering retention of the limb incompatible with life or comfort; avulsion of limb; compound fracture; compound dislocation; fracture with great comminution of bone; laceration of important vessels; extensive contusion; extensive laceration; gunshot injuries; aneurysm; effects of heat and cold; gangrene; extensive bone disease; tumors; elephantiasis; tetanus; snake bite; deformities."—Bickham's *Operative Surgery.*)

4. *Degrees of Burns.*—Dupuytren's classification: *First degree,* reddening of the skin. *Second degree,* blistering. *Third degree,* destruction of the epidermis, Malpighian layer, and papillæ of the derma. The sensitive nerve terminals are exposed; consequently this is the most painful degree. The sweat and sebaceous glands and hair follicles are not destroyed, and from these epithelium spreads in healing, so that repair is rapid, and the scar is not a contracting one. *Fourth degree:* the whole thickness of skin and part of the subcutaneous tissues are destroyed. *Fifth degree:* the muscles are injured. *Sixth degree:* the whole limb is charred.

Treatment.—General: If carbonic-oxide-poisoning is present, artificial respiration and administration of oxygen. For the relief of shock, opium and stimulants are called for.

Local: For burns of the first degree, powder with boracic acid. Puncture blisters, and cover the part with an antiseptic dressing.

Burns of deeper degrees than the second must be made aseptic with 1 in 1,000 perchloride of mercury. Carbolic acid is absorbed readily, and must not be used. Antiseptic gauze dressings should then be used. Picric acid (20 grains to 1 ounce of water) is used as a dressing. It lessen the pain, and can be left on two or three days. The continuous bath may be used. If the burn be of any size, it should be skin-grafted, as the scars of burns contract very much, and may produce deformities. —(*Aids to Surgery.*)

Opium is not contraindicated.

5.

REDUCIBLE SCROTAL HERNIA.	CONGENITAL HYDROCELE.	HYDROCELE OF CORD.
Impulse on coughing.	No impulse, unless combined with hernia.	No impulse, unless actually in abdominal ring.
Percussion clear if intestinal, dull if omental.	Percussion dull.	Percussion dull.
Ring and inguinal canal occupied, spermatic cord obscured.	Ring and canal clear.	Ring and canal usually clear.
Intestine to be felt, and returned with slip and gurgle, and remains up till effort is made, when it returns from above.	Fluid to be felt, and readily returned when patient lies down, and reappears slowly when he stands up, filling from below.	Small, ovoid, elastic tumor, connected with but movable upon spermatic cord.
Opaque.	Translucent.	Translucent.
Testicle below tumor.	Testicle behind tumor.	Testicle below tumor.
Any age.	Childhood.	Childhood.

—(Heath's *Surgical Diagnosis.*)

IRREDUCIBLE SCROTAL HERNIA.	HYDROCELE.
Sausage-shape.	Pyriform.
Intestine clear, omentum dull on percussion.	Dull on percussion.
Intestinal or knotty in feel, according to contents.	Elastic or fluctuating.
Testicle below tumor.	Testicle behind tumor.
Opaque.	Translucent.
Sudden.	Chronic.

—(Heath's *Surgical Diagnosis.*)

Hernia is a protrusion of an internal viscus through an abnormal opening in the parietes.

Bassini's operation: "An incision 2½ inches long is made over the inguinal canal, exposing the structures of the cord and the external oblique. The external oblique fibers are split from the apex of the external ring to expose the canal. The sac is found, opened, emptied of its contents, and isolated from the structures of the cord up to the internal ring. If the hernia is irreducible, the intestine is freed and returned to the abdomen, omentum being ligatured and removed. The neck of the sac is then transfixed and tied with silk, and the fundus removed. The stump returns to the abdomen, three or four stitches are then passed through the conjoined tendon and arched fibers of the internal oblique and transversalis muscles above, and the deep part of Poupart's ligament below. These are tied behind the cord. The external oblique is then sutured in front of the cord, leaving just sufficient opening for it to pass through without pressure. The skin is then closed by a continuous stitch. The patient should be kept in bed for three weeks, and should not exert himself for at least six weeks. If the wound has suppurated, or if the case is one in which the abdominal muscles are weak, it is advisable that a light truss should be worn afterwards for six months."—(From *Aids to Surgery.*)

6. FISTULA IN ANO.—*Classification:* There are four varieties: (1) The *complete*, which opens into the rectum internally and on the perineum externally; (2) the *external incomplete* or *blind external*, which opens on the perineum but not into the rectum; (3) the *internal incomplete* or *blind internal*, which opens into the rectum but not on the perineum; (4) the *horseshoe* fistula, which extends around the rectum and opens on each side. The internal opening is generally between the two sphincters, but may be above the internal sphincter and below the external sphincter. There may be several pockets or side tracts extending in different directions.

Treatment: This consists in "the conversion of the fistula into an open wound so that it may heal from the bottom. A grooved director is passed through the fistula into the rectum, and the overlying tissues severed with a bistoury. The sphincter should never be cut more than once, because of the danger of incontinence. All branching sinuses likewise should be opened, and all fibrous tissue, with undermined skin, cut away with scissors. The bleeding is then checked, and the wound packed with iodoform gauze. If the fistula is lined with mucous membrane it must be completely excised. A blind external fistula may be excised and the wound sutured. A blind internal fistula may be converted into a complete one and treated as above. The bowels are confined for the first three or four days and the wound dressed after each defecation, being irrigated with creolin and repacked with iodoform gauze."—(Stewart's *Surgery.*)

7. *Congestion* is excess of blood in the more or less dilated blood vessels of a part.

Inflammation is the name given to the series of changes occurring in a part as the result of injury, provided that the injury is not sufficient to kill the part.

An *aneurysm* is characterized by a pulsation, which is expansive; if firm pressure is made on the artery above the aneurysm the pulsation ceases and the swelling disappears; on relaxing this pressure the pulsating enlargement promptly reappears. Pressure on the artery below the aneurysm causes the enlargement to increase in size; by placing a stethoscope over the aneurysm, a bruit may be heard. In the case of an *abscess* over a vessel, there may be a transmitted pulsation, but it is not expansive; the pulsation ceases when the abscess is lifted away from the vessel; pressure on the proximal side does not cause the growth to disappear; there is never a true bruit.

Abscess should be opened as soon as possible.

Aneurysm is treated *medically*, by lowering the diet, especially the quantity of fluid; iodide of potassium or calcium chloride may be given. *Surgically*, complete extirpation of the sac is advised; or ligature of the artery, or compression of the artery may be tried.

8. "*Treatment of empyema* should be undertaken without delay. Aspiration seldom cures, but may be undertaken where the dyspnea is great, and an anesthetic given afterwards for the excision of a piece of rib. Drainage is always necessary, and is best done by excising a portion of the fifth or sixth rib in the mid-axillary line. The patient should be allowed to come round quickly from the anesthetic, so that the coughing which occurs will expel the masses of coagulated lymph and help to expand the lung. A big drainage-tube is then inserted. Daily dressings are necessary, but irrigation of the cavity is seldom needed. If, because of delay in treatment the cavity does not soon close, Estlander's operation, or some modification, must be performed. The wound must be enlarged and a number of ribs exposed, and sufficient of them removed to convert the cavity into a pyramidal one, the base of which is the open wound. This is packed with gauze and allowed to heal from the bottom. If the operation has to be extensive, the flaps are allowed to fall back upon the granulating surface of the lung, and in these cases marked scoliosis and weakness of that side of the chest follows."—(*Aids to Surgery.*)

HYGIENE.

1. *Temperament* is the character of a person's physical constitution as affected by his mental disposition.

Idiosyncrasy is a special peculiarity of temperament or constitution which makes a person different from other persons.

Diathesis is a bodily condition by virtue of which a person is specially liable to certain diseases.

2. A *virus* is the specific poison of an infectious disease. Vaccine lymph is also called a *virus*.

3. *Parasitic diseases that may be caused by eating insufficiently cooked meats:* Infection by tapeworm, by trichina, and by echinococcus.

4. *In the management of lobar pneumonia* "ordinary ventilation is not enough. It is often better to place the bed directly at an open window, day and night, the patient being allowed to breathe the pure cold air; but his body should be protected from the cold by warm, light coverings. It is often better, when possible, to have the patient out of doors, in a tent, on a veranda or roof, and when this cannot be done, he should be given the benefit of the open air for a few hours each day. The relief experienced by the patient in a severe condition from removal to the open air is remarkable, and it undoubtedly makes recovery possible in many cases that are hopeless without it."—(French's *Practice of Medicine.*)

5. *Period of infectivity of diphtheria.* "The length of time during which a patient who has suffered from diphtheria may remain infectious is very variable. The bacillus has been found to be absent from the throat as early as the end of the second week. In view of the uncertainty which attends the recovery of the bacillus from the throat it is well to consider that all patients are infectious for at least six weeks, and no child should be allowed to return to school until eight weeks have elapsed from the beginning of treatment."—(McClure's *Handbook of Fevers.*)

6. The patient must be isolated; no one but the physician and nurse must enter the room; the physician should put on a large washable gown when he goes in, and remove it on leaving, at the same time washing his hands in a disinfectant; the nurse, when she leaves the sick room should also remove her clothes and put on others, at the same time disinfecting herself. At the termination of the disease everything should be disinfected; toys and books, etc., are better burned.

7. A *disinfectant* is an agent which restrains infectious diseases by destroying or removing the micro-organisms which cause them.

8. *Formaldehyde* is a good surface disinfectant, has poor penetrating qualities, does not destroy fabrics and injure objects, and is non-toxic. *Sulphur dioxide* damages textile fabrics, tarnishes metal objects, and is very poisonous.

To disinfect a room by formaldehyde: (1) By Trillat's apparatus, which "allows the solution of formalin to flow in a fine stream through a copper coil heated to redness by a flame beneath, and the gas and vapor passing directly into the room. The apparatus may be

operated outside of a room, and the amount of gas liberated depends directly upon the strength and quantity of the solution evaporated. (2) In Schering's method the solid paraform is heated in a receptacle over an alcohol lamp, and is especially valuable in disinfecting small rooms, closets, etc. (3) The cheapest and most common form develops the gas directly by the oxidation of methyl alcohol, the vapors of the latter passing over and through tubes or coils of heated metal. The amount is uncertain and results indefinite."—(*Cyclopedia of Medicine and Surgery.*)

To *fumigate by sulphur dioxide:* For each 1,000 cubic feet of space, three pounds of sulphur are burned, care being taken to prevent accidents. In all cases all apertures and crevices of the room should be closed, all closets, drawers, or other receptacles opened; and after the fumigation the room should be well ventilated and thoroughly cleansed with a solution of corrosive sublimate.

9. *Diseases, the prevention of which would lengthen the average of human life:* Tuberculosis, typhoid, pneumonia, syphilis, gonorrhea, malaria, yellow fever, diphtheria, influenza, cerebrospinal meningitis, septicemia, pyemia, dysentery, cholera, plague, smallpox, measles, scarlet fever, hydrophobia, leukemia, endocarditis, hypertrophy of the heart, angina pectoris, heart-block, arteriosclerosis, aneurysm, asthma, pneumokoniosis, emphysema, pleurisy, empyema, gastric ulcer, gastric cancer, appendicitis, constipation, cirrhosis of liver, abscess of liver, cholecystitis, gallstones, tumors of pancreas, peritonitis, nephritis, pyelitis, diabetes mellitus, alcoholism and addiction to drugs, various poisonings, sunstroke, and industrial diseases.

10. *Bubonic plague* is an acute infectious disease associated with glandular enlargement, and due to the *Bacillus pestis* which is conveyed by fleas on rats.

To prevent the spread of the disease, the following routine was followed in Glasgow, during the epidemic of 1900: "(1) Within the infected area, ashpits were emptied thrice weekly and washed once a week with chloride of lime solution. (2) Back courts were hosed every night with chloride of lime solution. (3) A special inspection of the district was undertaken for the detection of dirty houses, entries, etc., and for the overcrowding of houses. (4) Medical inspection of the district was carried out and the inhabitants of infected buildings and all 'contacts' were offered injection with Yersin's serum or Haffkine's vaccine, while all suspected cases were visited with their own medical attendants. (5) Handbills were distributed offering the service of the medical staff at any time. (6) the crews of all ships were inspected on arrival in port. (Fumigation of infected houses was carried out by liquefied SO_2 for twelve or twenty-four hours, after which the house was entered and all articles of bedding, clothing, etc., were wetted with a 2 per cent. solution of formalin (1 gallon of a 40 per cent. solution of formaldehyde to 50 gallons of water), removed to the sanitary wash-house, and then boiled or steamed. All articles which could not be boiled or steamed were burned. (8) All houses where cases had occurred or from which contacts were removed were sprayed with the formalin solution, as were also the lobbies and entries. (9) Clinical demonstrations were given daily to medical practitioners at the hospital. (10) A pamphlet descriptive of the varieties of the disease was distributed among the medical practitioners of the city. (11) Physicians to out-patients at the various hospitals were specially circularized. (12) A campaign against rats was entered upon; rat-catchers were engaged and the bodies of rats were investigated for the signs of plague. The sewers of the hospital were treated with liquefied SO_2, and the rats driven from the hospital by this method. (13) The bodies of those who died from plague were drenched with formalin and enclosed in an airtight leaden shell before burial. (13) The holding of wakes over any dead bodies was prohibited."—(McClure's *Handbook of Fevers.*)

Ichthyosis with Superficial Ulceration of Tongue.—J. L. Bunch reports the case of a boy aged twelve years who had generalized ichthyosis of the trunk, limbs, and face. There were marked roughness and thickening of the skin and hyperkeratosis of the palms. The boy had a chronic glossitis, with superficial ulceration, which had been present all his life, but varied somewhat in severity at different times. His mental capacity was somewhat deficient.—*Proceedings of the Royal Society of Medicine.*

Therapeutic Hints.

A Chalk Paste and Its Indications.—Unna has devised a new employment of the chalks by combining them with mucilage of gum arabic as follows:

℞ Calcium carbonate, 40 grams.
Zinc oxide, 20 grams.
Mucilage of gum arabic, 20 grams.
Glycerin, 10 grams.
Lime water, 10 grams.

To this may be added a small amount of thymol or menthol, to keep it. It forms a homogeneous paste which leaves a firm, dry mass upon the skin. Its chief indications are the following: It causes the rapid drying up of large edematous, erythematous, and oozing surfaces. Severe edema of the face, neck, and extremities in the course of chronic eczema is a condition specially suited for the paste. A second indication of great importance is the chance to dry up all fat salves and fat pastes by covering them with the chalk paste. This is especially valuable in the case of very irritating applications, such as chrysarobin, as it limits the secondary inflammatory action upon the adjacent parts of the skin. A third indication for the chalk paste is to keep the skin dry about wounds, oozing skin affections, and fistulæ.—*Dermatologische Wochenschrift.*

For Renal Colic.—G. Sabatini credits A. Robin with the following prescription:

℞ Morphine hydrochloride, 0.05 gram.
Potassium bromide.
Cherry-laurel water, āā 10 grams.
Syrup of ether (Belg. phar.), 30 grams.
Valerian water (Fr. phar.), 110 grams.

M. et. Sig.: One tablespoonful every hour.—*Il Policlinico.*

The Treatment of Pneumonia.—H. J. Mathison recommends the administration of the following:

℞ Potassium iodide, ʒ j.
Creosote, ʒ s.
Alcohol, ʒ ij.
Fluid extract of licorice, ʒ iij.
Water, q. s., ad ʒ vj.

M. et Sig.: One tablespoonful every four hours.—*The Polyclinic.*

A New Method of Obstetrical Analgesia.—Ernesto de Aragón reports good results following the use of hypodermic injections of the following solution:

℞ Heroin hydrochloride, 0.005 gram.
Scopolamine hydrobromide, 0.0004 gram.
Neutral, atropine sulphate, 0.0003 gram.
Sparteine sulphate, 0.01 gram.
Polyatomic alcohol, 0.5 to 1 c.c.

The above is sufficient for one hypodermic injection.—*Revista Medica Cubana.*

Treatment of Heart Weakness.—Moczulski is said to recommend the inhalation of a mixture of 10 drops of tincture of strophanthus in 30 c.c. of water, kept at a temperature of 40° C. The following is administered by mouth:

℞ Tincture of strophanthus, 2 grams.
Tincture of nux vomica, 8 grams.
Compound spirit of ether or anisated solution of ammonia, 10 grams.

M. et Sig.: 10 to 20 drops every 2 hours.—*Boletín de la Revista Ibero Americana de Ciencias Médicas.*

LYMPHANGIOMA AND RADIUM.*

BY ROBERT ABBE, M.D.,

NEW YORK.

IN working out the problem of the utility of radium in the surgical field, it is evident that its supreme efficiency lies in its specific action. By this is understood the effective change, wrought on tumor cell growth, neither destructive nor constructive, but alterative. That there is such a specific action is shown in several types, most typically in myeloid tumors, massive growths of soft tissue, constituted of marrow cells of bone, which have overgrown, absorbed the bone surrounding them, and destroyed its form and usefulness, thus by its destruction justifying its classification as malignant.

When the proper dosage has been given the tumor shrinks, gritty bone forms here and there in the pultaceous mass, general ossification follows, and the bone takes on its normal outlines as the shrinking progresses. Finally, the restored bone remains normal indefinitely, cases remaining well ten years to date.

This same specific action is also shown in basal cell epithelioma, in round cell sarcoma, in all papillomas and hyperkeratoses, and in myomas of the uterus. This legitimately called specific action is not a destructive, but a restorative one.

To this growing list I would add one that takes up a new field which though not so large is equally important—that of lymphangioma. The first case that interested me was one of a massive tumor of the tongue which I will illustrate by a photograph taken some time after it began to improve, but while it still showed the characteristic signs. It is a well-known type of tumor of the tongue which combines overgrowth of blood and lymph vessels, plus coincident cell hyerplasia making a massive affair, unmanageable and deforming—a hemolymphangioma. For this trouble so great an authority as Butlin voices the experience of the world, that there is no resort but that of cutting out great masses from it, or if possible all of it. Experience further shows, as I shall soon demonstrate, that even this sometimes fails.

FIG. 1.—Lymphangioma of the tongue before treatment by radium.

FIG. 2.—Lymphangioma of the tongue (same case as Fig. 1) cured by radium

The case shown (Figs. 1 and 2) was that of a young man who at seven years of age began to have

* Read before the American Surgical Association, June 11, 1915, at Rochester, Minn.

an enlargement on the left half of the tongue. In three years it was a foul overgrown mass, intermittently bleeding severely and affecting seriously his speaking and eating. At fourteen years of age I saw him and applied radium to it. In two months it showed notable change for the better. At that time I showed him hopefully to the Practitioners' Society and took this photograph. Year by year it shrank, under occasional treatments, given only at three month intervals. In four years I again showed him to the society—cured. The tongue surface has its normal color and papillary appearance, showing a retrograde to normal.

To the uninitiated four years sounds like a long time to give treatment, but one must remember that in all new fields the observer has to feel his way along cautiously and judge of the proper curative dosage of radium, without injury to the tongue. At the present time much of the same result could be obtained in perhaps a quarter of the time.

In a second case a tumor appeared in the anterior part of the tongue of the daughter of a Boston physician. This was cut out by able surgeons. It recurred in two months. After it had grown larger and more threatening it was again cut out and pronounced sarcoma. It recurred, and was for the third time cut out and microscopically regarded as lymphangioma. The future seemed hopeless for cure by excision. She was brought to me with a bean-shaped recurrence in the scar. This I radiumized well by Wickham's crossfire method for one hour. It rapidly melted away in six weeks and the tongue has remained normal for over a year.

A third case of hemolymphangioma of the tongue came to me recently in a man who was annoyed by a small raised purple growth on the side of his tongue, which was to a large extent naevus, but had the firm consistency of a pearly tissue combined with the enlarged vessels. Its recent appearance and characteristic quality on close study decided me to treat it without excision as a hemolymphangioma. One radium application to create good reaction has produced a cure, cell angiomatous and overgrown lymph structure being replaced by a simple cicatrix.

An unusual type of extensive nevus of the entire right leg in a seven year old boy was presented to me last year (Fig. 3) which had developed hyperkeratosis over much of its surface, with deep lying masses of tissue, varying from an eighth to a half inch in thickness; and in many places ulcerated and bleeding from a curious granular surface of purplish color. The child had been taken to many surgical clinics in the country with hopeless prognosis, and was finally referred to me by Dr. J. B. Murphy of Chicago. I recognized a condition analogous to that of the lymph hemangioma of the tongue, and asked the critical diagnosis of Professor George T. Elliot without prejudicing his opinion by my own. He studied the margins of the surfaces, which showed raised and striated crêpe-like angioma, and called my attention to great numbers of small white vesicles scattered everywhere which could be nothing but lymphangioma, combined with the hemangioma structure, thus fixing the diagnosis and explaining the unusual exulcerated masses and ridges over much of the diseased area, and which were not arranged anatomically like vessels, but like overgrown lymph channels choked with cells. I then expressed the belief that radium ought to cure the lymphangioma as it certainly would the nevoid condition. I made many color photographs of the lesion for identification and show one plain photograph here.

The technical methods of using radium taxes the operator's ingenuity, but being a new field will not be detailed here. Suffice it to say that steady progress has been made and a promise of ultimate cure can be asserted.

Another rare type of *pure* lymphangioma was presented to me by Dr. George T. Jackson of New York and Dr. Engman of St. Louis in the case of a little girl who had a congenital group of vesicles on the skin of her neck below the hair line on the right side, extending downward two inches and a half by an inch and a half wide (Fig. 4). In

Fig. 3.—Hemolymphangioma in process of cure by radium.

this space were packed a hundred white glistening vesicles, the size and height of rice grains, constituting a notable deformity. Occasionally one would rupture, occasionally one would turn black and dry up. I am inclined to explain the latter by union of a capillary blood vessel with the dilated lymphatic, thus in a feeble form simulating the other enormous tumors with interchange of the lymph and blood capillaries. One application of radium to this patch of pure lymph angiomata for one hour and a half caused a sharper action with rapid disappearance of all but six marginal vesicles, to which at four months' interval a second treatment has been given. Photographs of plaster casts taken

before and after treatment are most convincing.

A second case of pure lymphangioma of the skin of the neck of a four year old child has also received radium treatment lately. It is the exact counterpart of the one just narrated. This plaster

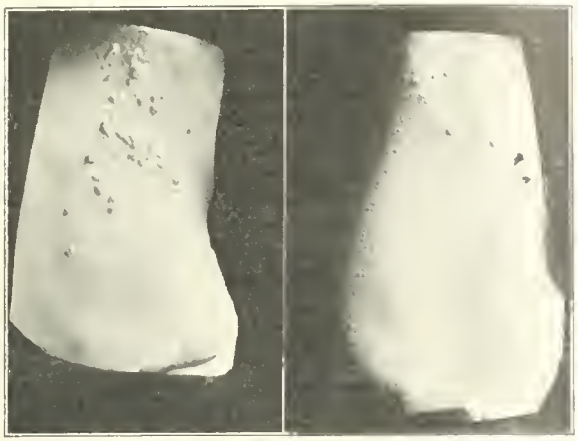

Fig. 4.—Pure lymphangioma of the neck, before and after one radium treatment.

cast shows the location. Not the least interesting occurrence was the occasional filling of white vesicles with blood, or at times breaking and discharging clear fluid. Before coming under my care the patch of vesicles, measuring one inch in diameter, had been treated, first by caustics and then by freezing. A keloid scar remained at the margin of which were a few lymph vesicles. A most interesting statement was made by the mother that a new crop of vesicles had come up through the scar. This shows that the caustic had not obliterated the lymphangioma.

In this brief series of six cases my endeavor has been to show that by culling out similar types from thousands of various surgical cases treated by this wonder working agent, we are slowly accumulating evidence of the unique and specific action of radium, whose essential output is a discharge of beta rays, negative electrons—which in some mysterious way restore order to the disordered cell growth.

The public hue and cry for a specific cancer cure has but a remote interest to the scientist, who uses radium only for what beneficial effects he obtains. Certain it is that in the broadening field of its successes it fills a need that no other agent does. Incidentally it transpires that the virulent squamous cell and scirrhus types of cancer, so dreaded by all, is not cured by radium as now used.

The output of radiant energy from radium and that from the Röntgen tube are alike as far as the neutral gamma radiation goes, but this has been shown to be efficient only by its development of beta rays—the negative electrons—which alter the cell growth. On the one hand the *x*-ray output is a gamma discharge, creating betas in the tissue on meeting resistance; on the other, radium emits a free discharge of beta electrons with enormous energy and short range. This explains satisfactorily why the local action of radium is so intense and efficient on lesions lying near or upon the surface, and why it also reaches deeper, when the beta rays are screened off, and long exposures are permitted. In the lymphangioma structures which I have described great depth is not desired in treatment. Hence the success following its application.

What the rationale of its efficiency is must be conjectured. Certain it is that charging up the disordered cells of the tumor with negative electric particles shot into them in proper quantity completely changes their habit of growth and restores them to permanent healthy action.

THE *X*-RAY TREATMENT OF RINGWORM OF THE SCALP.

By George M. Mackee, M.D.,

New York

Instructor in Dermatology, College of Physicians and Surgeons, Columbia University; Chief of the Department of Dermatology and Syphilology, Vanderbilt Clinic,

and

John Remer, A.M., M.D.,

New York,

Radiologist and Clinical Assistant, Department of Dermatology and Syphilology, Vanderbilt Clinic.

The geographical distribution of ringworm of the scalp is not uniform. In this country, for instance, the Mississippi Valley is comparatively free of the disease, and when the affection does occur in this locality it readily responds to the ordinary therapeutic measures. On the other hand, the disease is exceedingly common in New York, especially among the poor, and, as is well known, constitutes one of the most recalcitrant of dermatological affections.

We desire to emphasize the inefficiency of the older methods of treatment. Such methods consist, briefly, in pulling out the affected hairs as fast as they grow and applying strong antiparasitic agents to the diseased areas. This procedure is practical in intelligent and wealthy families, where, through the perseverance of the nurse, a cure may be effected in from a few months to three years. For obvious reasons, however, such a method is impracticable among the poor, and as a result the disease remains more or less active until puberty, when it disappears spontaneously.

Fig. 1.—Single patch of small-spored ringworm. Shows scaliness and broken-off hairs.

(From the Department of Dermatology and Syphilology, College of Physicians and Surgeons, Columbia University.)

Now, inasmuch as the disease is contagious, the afflicted children are rightly refused admission to the schools, with the result that a great many individuals are deprived of the desired and essential elementary education at a time when the brain is

Fig. 2.—Disseminated small-spored ringworm. The patches are numerous but for the most part discrete. On the side of the head, however, the lesions are becoming confluent.

most receptive. In the majority of instances the disease is acquired early in life, under the age of six or eight, and continues to the age of from twelve to fifteen. And during this entire period the child receives very little, if any, schooling. Inasmuch as most children of the poor obtain positions at the age of sixteen or less, it may be seen that elementary education in these instances is sadly neglected. Now, this is not just to the State nor to the individual. The handicap to the individual, occasioned by the loss of an early education, needs no comment. But it is doubtful if the State has ever seriously considered ringworm as a cause of illiteracy, or if it has, it has shown no disposition to remedy matters. Another fact that should be considered is that children with tinea tonsurans, although kept out of the schools, do mingle with and infect other children after school hours. In this sense such individuals are a real menace to the community. It must not be forgotten, too, that domestic animals, cattle, etc., may be infected and become carriers of the disease.

Before entering into a discussion of the *x*-ray treatment of ringworm of the scalp, we desire to call attention to some facts regarding the disease that are not sufficiently appreciated by medical practitioners. The affection is not always such a mild disease as physicians are wont to believe, nor is the clinical diagnosis easily made in all cases. Every physician, of course, recognizes the typical patch of ringworm of the scalp which manifests itself by slight erythema, scaliness, and broken off hairs (Fig. 1). Disseminated ringworm, especially when confluent, produces quite a different picture (Figs. 2, 3, and 4). The large-spored fungus is capable of causing pus formation and in this variety of ringworm vegetating tumors containing multiple pus foci are frequently encountered (Figs. 5, 6, 7, and 8). These tumors are called kerions. The small-spored fungus never produces permanent alopecia nor is the affection serious. On the other hand the large-spored variety may often cause permanent loss of hair through destruction of the follicles. Occasionally this follicular destruction tends to bring about a spontaneous cure. Contrary to the benign, although obstinate course of the small-spored variety, the large-spored ringworm may prove quite serious, as illustrated by the following example:

The patient was a boy, about eight years of age. He contracted the ectothrix variety of ringworm from a cow while he was on his summer vacation in the country. The child was under the observation of Drs. Fordyce and Howard Fox and was referred to us for *x*-ray treatment. When first seen the entire scalp was covered with crusts, which, when removed, revealed innumerable split-pea to palm-sized, boggy tumors which exuded a purulent fluid. In addition the pus had collected under the scalp, lifting the latter from the skull. The little fellow was emaciated, highly nervous and irritable, and ran a high temperature. His condition was so serious that his family's physician made multiple incisions for the purpose of drainage and one palm-sized tumor was completed ablated. The entire scalp was later treated by the intensive *x*-ray method at one sitting, and the lad made a prompt and uneventful recovery.

In closing this part of the discussion we desire to call attention to the so-called bald ringworm and black-dot ringworm, varieties that are not infrequently mistaken for alopecia areata.

The use of the *x*-ray in tinea tonsurans is based

Fig. 3.—Confluent ringworm. Here, every hair in the head is diseased and broken off. This is the same patient as shown in Fig. 1. The single diseased area shown in Fig. 1 was depilated and the falling hairs infected the rest of the scalp. The dark spot in the center of Fig. 3 is the hair returning after the *x*-ray treatment. This hair is darker than the untreated hair.

upon its ability to cause a defluvium—to make the hair fall out. The *x*-ray does not have a destructive effect on the fungus, although it is possible that in some way it so modifies the soil that the organism finds a less favorable medium upon which

to grow. In any event, most of the spores are removed with the hair and those remaining disappear or are destroyed by the use of antiparasitic remedies before the hair regrows at the end of about three months.

In general there are two ways in which the *x*-ray can be employed for this purpose—namely, the divided dose and the massive or intensive dose methods. With very few exceptions the former is the procedure used in this country, while in Europe the latter method has been employed since it was advocated by Sabouraud and Noiré in 1904.

The older method (divided-dose) is unscientific and has been relegated to the past. We desire to remind the reader that we are dealing solely with the treatment of tinea tonsurans. It is only employed now by those who will not or cannot modernize their technique. It precludes accurate direct measurement and cannot be employed to produce a defluvium of the entire scalp, at least not without considerable danger. Its use, therefore, is limited to the individual treatment of one or more areas

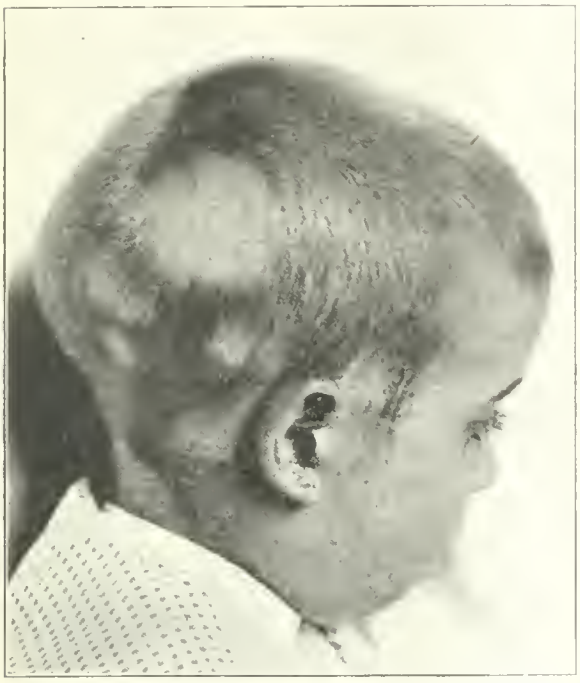

Fig. 4.—Multiple patches of small-spored ringworm.

and even here the result is uncertain and unsatisfactory; at least the results are not constant. We will support these statements by adding that when individual lesions are treated, the diseased hairs, when they fall out, are scattered over the scalp and new patches of disease develop. This may be prevented, to a certain extent at least, by applying adhesive plaster to the treated area after the application of the *x*-ray. This is removed in three weeks with the loosened hair. Fig. 1 represents a case of ringworm of the scalp. Fig. 9 shows the same patient after a local defluvium produced by a single *x*-ray treatment. The original patch of ringworm may still be seen and it will be noticed that the hair has been removed for quite a distance from the margin of the lesion. Careful inspection of the photograph will also demonstrate that the disease has involved the hairs at the margin of the bald area. The disease then spread over the scalp as shown in Fig. 3, which was taken a few weeks subsequently. Here the affection is disseminated and confluent and there is not a single healthy hair remaining on the head. The entire scalp was then depilated by means of the modern technique, with the result as shown in Fig. 10. In three months the hair returned and the child has since been en-

Fig. 5.—Large-spored (ectothrix) ringworm, producing a boggy swelling containing numerous pus foci. Such a tumor is known as a kerion.

tirely free of the disease. It is well known that if the *x*-ray produces a marked erythema, the hair will not return and visible atrophy and even teleangiectasia may be the sequelæ. With the older technique permanent alopecia may occur even in the

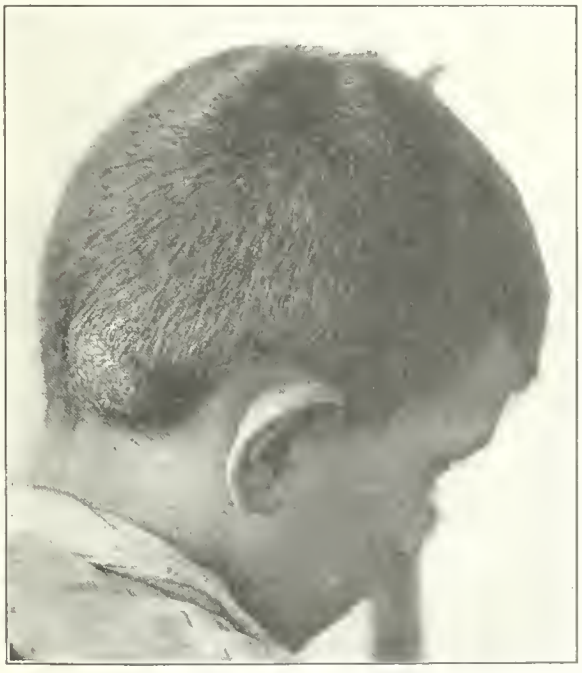

Fig. 6.—A typical kerion.

absence of a preceding erythema. The reason for this is possibly explained by the following hypothesis: If administered at one sitting it requires from 4 to 5 Holzknecht units to produce a complete temporary defluvium. On the other hand, if this

amount is divided into eight treatments which are administered twice weekly, depilation will not result; at least this has been so in our experiments. In other words, by the divided-dose method considerably more ray is used than when a single epi-

Fig. 7.—Here the ectothrix has produced a condition resembling eczema. The skin is thickened and scaly with here and there a follicular pustule.

lating dose is given and, of course, this additional ray is unnecessary and injurious. The older tech-

Fig. 8.—Large-spored ringworm resembling seborrhoeic eczema. Here the scales or crusts are yellow and waxy and the skin is somewhat thickened.

nique consists of employing a small amount of *x*-ray (too small to be accurately measured) two or three times a week until depilation occurs. Now it must be remembered that after the epilating dose has been administered there is an interval of three weeks before depilation occurs. It is possible, therefore, that in the divided dose method the *x*-ray is being applied during this period of latency and that this extra dosage may be enough to produce permanent baldness, atrophy and even teleangiectasia without the advent, necessarily, of an erythema.

Our German colleagues were the first to advocate and employ large and carefully measured doses of the *x*-ray in radiotherapy. In 1904 attention was called to the practical application of the intensive method in the management of tinea tonsurans by Sabouraud and Noiré, who were able to show remarkable results. Subsequently nearly all the European clinics treated the disease in this manner with uniformly good results. In fact, comparatively speaking, and as a direct result of this modern technique, tinea tonsurans has been almost eradicated from several European cities. But in spite of the reliable technique of our European confrères and the excellent results obtained by them, it is only within the past few years that American radiolo-

Fig. 9.—Same patient as shown in Fig. 1, after a local *x*-ray treatment. The ring in the bald area is the former margin of the disease.

gists have entered this field. Even at the present writing, however, there are very few clinics in America where individuals afflicted with tinea tonsurans can receive the benefit of modern *x*-ray therapy without expense to themselves.

While it is true that most of the New York clinics are equipped with *x*-ray apparatus and ringworm cases receive *x*-ray treatment, the results are extremely unsatisfactory for the simple reason that the technique has not been modernized. Under the old régime, while a small proportion of cases are cured, most of them are practically unaffected.

As an example we desire to relate the following incident:

Each child of a family of seven had a disseminated ringworm of the scalp. The children were treated at various clinics with and without the *x*-ray, but the disease was not controlled—in fact, no hope was given of a cure by any method. The children were, of course, refused admission to the schools, and the father, fearing the results of il-

literacy, managed to borrow enough money to take his children to London, where they were treated in Sequeira's clinic.

Now such an example does not reflect credit upon our city nor upon American dermatology. Unfortunately these cases relapsed and the treatment must be repeated. Such a result is, however, the exception rather than the rule.

The following technique is the one in use at Dr. Fordyce's clinic. There is nothing original about the method, it being the result of the work of many investigators in the same field—Sabouraud and Noiré, Holzknecht, Kienböck, Adamson, Sequeira, Hampson, Pirie, Corbett, Coolidge, Macleod, and many others.

The first step, for convenience, is to cut the hair close to the scalp. The next step is to divide the scalp into four equal sized triangular-shaped areas in the following manner: A mark is made (with a skin pencil) about 2 inches inside of the hair line above the forehead in the median line (Figs. 11

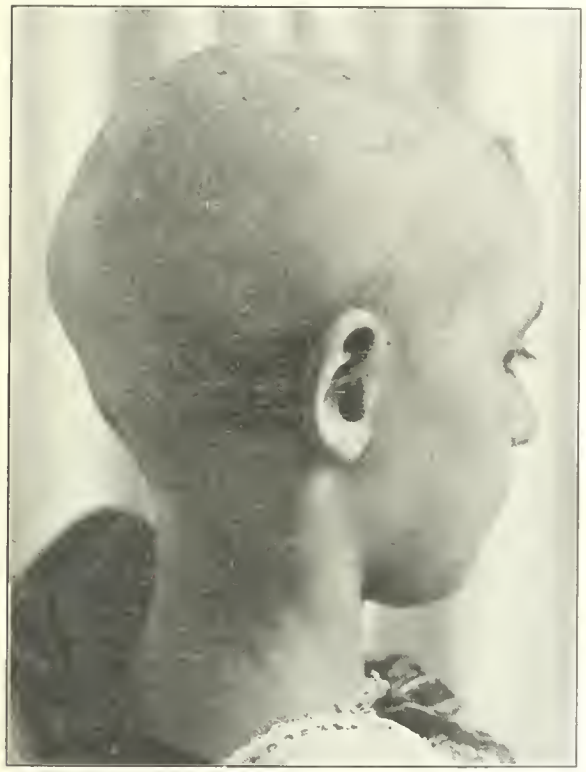

Fig. 10.—Same patient as shown in Figs. 1, 3, 9 and 11, after complete defluvium by the Kineböck method. The disease disappeared shortly after the hair fell out; the hair began to regrow in less than three months and there was no relapse.

and 13). This we will designate point A. A steel tape measure is then placed with zero on point A and stretched along the median line over the vertex to the neck. At 10 inches another mark is made—point B (Fig. 11). This will usually be about 2 inches inside of the hair line of the neck, but will vary somewhat in accordance with the size of the head. Points A and B should be adjusted so that they are about the same distances inside of the anterior and posterior hair lines. As a matter of fact, A and B, in some instances, may fall exactly at the hair line, but this makes no difference so long as the distance between them is exactly 10 inches. Point C is then indicated by a mark in the middle line exactly half way between points A and B (Figs. 11 and 12). On every skull there is a flat surface just anterior to the occiput and point C will fall from 1 to $1\frac{1}{2}$ inches in front of the center of this area. As a matter of fact it is a good idea to insist upon point C being exactly at this location and adjust A and B so that they will

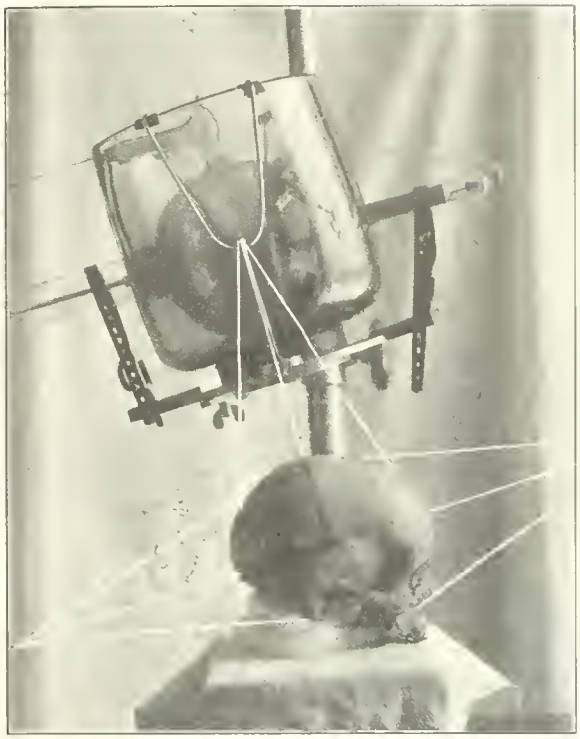

Fig. 11.—Showing Points A, B, C, and D. Also the lines drawn between the various points and how the angles of incidence are obtained.

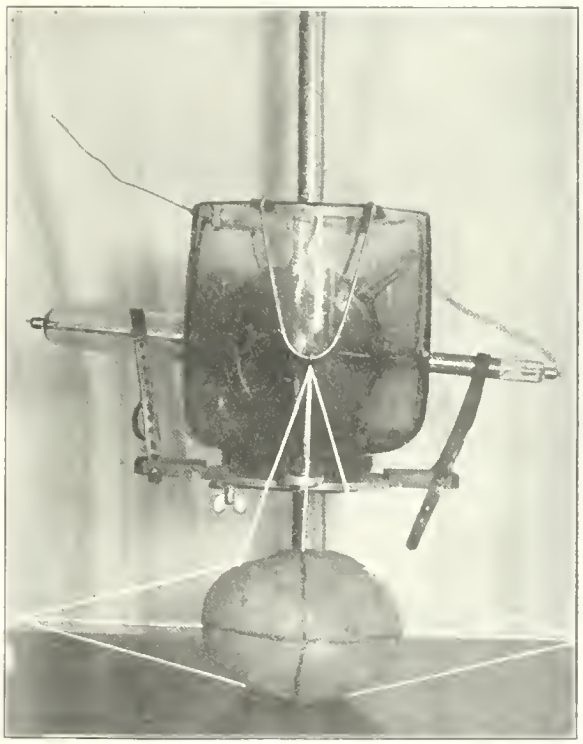

Fig. 12.—Showing Point C.

be just 5 inches anterior and posterior to C. Point D is then located just above and in front of the right external auditory meatus (Fig. 11). The exact position of this spot is found by measuring 5 inches from A, B, and C. Point E represents the

same location on the left side. It is essential that each point be exactly 5 inches from every other point, with the exception, obviously, of the distance between points A and B, which should be 10 inches.

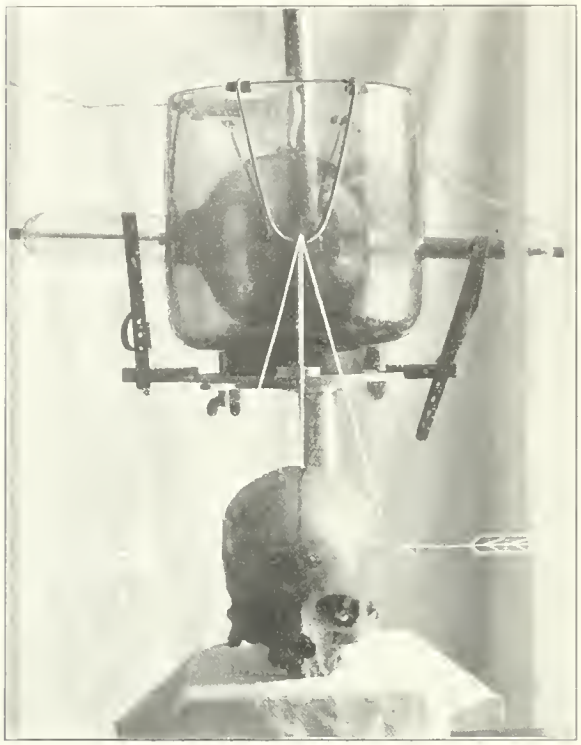

Fig. 13.—Showing Point A.

The next step is to draw lines between the various points (Figs. 11, 12, and 13). This will divide the scalp into four triangular-shaped, equal areas. The reason for this will be made clear later.

Next, each point—A, B, C, D, and E—receive an epilating dose of *x*-ray in the following manner:

For point A the child lies on its back on a table. The entire face below the hair line is protected by a lead mask. The tube is placed with the anode exactly over and $6\frac{1}{2}$ inches from point A (Fig. 11). It will be seen that the vertical rays will strike point A, while half of the oblique rays will fall upon the anterior portion of the scalp, and the remaining half will strike the protecting shield on the face and be wasted (Fig. 11). The measuring pastille is now placed on point A, and the epilating dose administered.

Points B, C, D, and E are now to receive the epilating dose in the same manner with the following exceptions: For point C the patient may recline on a table or sit upright on a chair. No protection is required. Here the oblique rays spread over the anterior, posterior, and lateral portions of the scalp (Figs. 11 and 13). For point B, the child may lie on his side on the table or sit in a chair with his forehead resting on the table. It is necessary to protect the neck, shoulders, and back. Here half of the oblique rays will reach the posterior portion of the scalp while the other half will spread over the shoulders and back (Figs. 11 and 12). For points D and E the patient lies on his side on a table and the ears, face, and neck are protected (Figs. 12 and 13). Here, as in points A and B, half of the oblique rays are lost.

It is of the utmost importance that each treatment be at right angles to every other treatment. For instance, an imaginary line drawn from the anode to point A will be at right angles to lines extending from the anode to points C, D, and E. Figs. 11, 12, and 13 will explain these angles better than words and, also, they will demonstrate that the lines drawn on the scalp between the five points aid one in quickly determining the correct angle.

A study of these illustrations will show, also, how the vertical rays strike the five points while the oblique rays from one treatment overlap and reinforce similar rays from other treatments. For instance, if a full epilating dose is administered to point E and to no other portion of the scalp, the hair will fall out over only a very small area (Fig. 14). But when similar doses are applied to points A, B, and C the oblique rays overlap and complete alopecia is the result (Figs. 10 and 15). In explanation it may be stated that point E, being in the field of vertical rays, receives the full epilating dose, while a point half way between E and B receives one-half an epilating dose. But this point also receives one-half an epilating dose when point B is treated. In this way the entire scalp, when the five points have been treated, receives a full epilating dose. Scientifically, the well-known laws of intensity being in inverse proportion to the square of the distance and directly with the size of the angle of incidence, account for the equal distribution of the dose. This method of treating the entire scalp by five exposures was originated by Kienböck and is exceedingly accurate, as shown by Adamson, Pirie, Sequeira, and many others.

For the purpose of determining the epilation dose, both the quality and quantity of ray must be estimated. There are numerous radiometers designed for the purpose of measuring the quantity, but we rely entirely upon either the Holzknecht or the Corbett radiometer. They both are modifica-

Fig. 14.—Showing the extent of hair loss as a result of an epilating dose applied to Point E. This is the same patient as shown in Figs. 1, 3, 9, and 10.

tions of the original Sabouraud-Noiré method of utilizing the change in color produced in platinocyanide of barium when under the influence of the *x*-ray. The Corbett radiometer, the most recent and most scientific quantity instrument, consists of

a series of colored glass tablets, each piece of glass representing the color assumed by the double-cyanide of barium after it has received varying amounts of exposure—in other words, they represent doses of *x*-ray measured in Holzknecht units.

Fig. 15.—Complete depilation in a case of disseminated ringworm by the 5-exposure method at one sitting.

The Sabouraud (barium) pastille is placed on the scalp and the *x*-ray is applied until the pastille matches in color the particular glass tablet that corresponds to the epilating dose (5 H). The pastille and the tablet are compared in a black chamber under the influence of reflected artificial light. The colored glass tablets are standardized by the tintometer and are both accurate and permanent. The Holzknecht instrument has a strip of celluloid which, colorless at one end, gradually assumes color which becomes deeper as the other extremity is approached. One-half of a Sabouraud pastille is placed under the celluloid strip, the other half is placed on the scalp and exposed to the *x*-ray. It is then compared with the half pastille under the celluloid and moved along the colored strip until the colors register. A scale of figures on the instrument allows a reading to be made in Holzknecht units. There are many technical details connected with the work that we cannot discuss here. Suffice it to say that in experienced hands this method of measuring the quantity is absolutely reliable.

In such delicate technical work it is, of course, advisable to utilize, especially in the beginning, as many safeguards as possible; therefore, it is advisable to work with a constant amperage, voltage, and milliamperage, and a fixed parallel spark gap, a fixed distance, etc. In our technique, however, we are constantly changing these factors and, therefore, disregard the indirect and depend entirely upon the direct methods of measurement of quantity.

Since the advent of the Holzknecht radiometer we have had no difficulty in estimating the quantity of ray employed. We have, however, had a great deal of trouble in measuring the quality, and this was entirely due to the impossibility of obtaining tubes that would maintain a constant vacuum during the treatment. Water and air-cooled tubes lessened the difficulty. The air-cooled hydrogen tube, also, has given good satisfaction. But the remarkable Coolidge tube has completely overcome all difficulties in this respect. This tube will maintain a constant vacuum with light or heavy currents for long periods of time and may be used on one case after another throughout the entire day. For the direct estimation of quality we utilize the Benoist penetrometer, aided by indirect instruments such as the Heinz-Bauer qualimeter, the milliamperemeter, etc.

We employ a "hard ray"; never less than No. 8 of the Benoist scale, and earnestly advise against the use of soft rays. The original epilating dose, as devised by Sabouraud and Noiré, (B 1 or H 5) was based upon the use of "hard rays," obtained by exciting a tube with a static machine. This fact has been generally overlooked and the use of "soft" rays has been one of the causes of bad results in the past.

We place the pastille on the scalp as advised by Hampson and others, instead of half way between the anode and scalp. There is no doubt in our mind that both accuracy and safety are enhanced by placing the pastille on the scalp. At half distance the slightest movement of the child will alter the relative positions of the head, pastille, and anode, and this will cause a faulty estimation of the dose. With the pastille placed on the scalp it makes no difference if the head moves a little closer to or a little further from the tube during the exposure. Lateral motion, however, must be avoided in any case. Furthermore, the changes in color are less

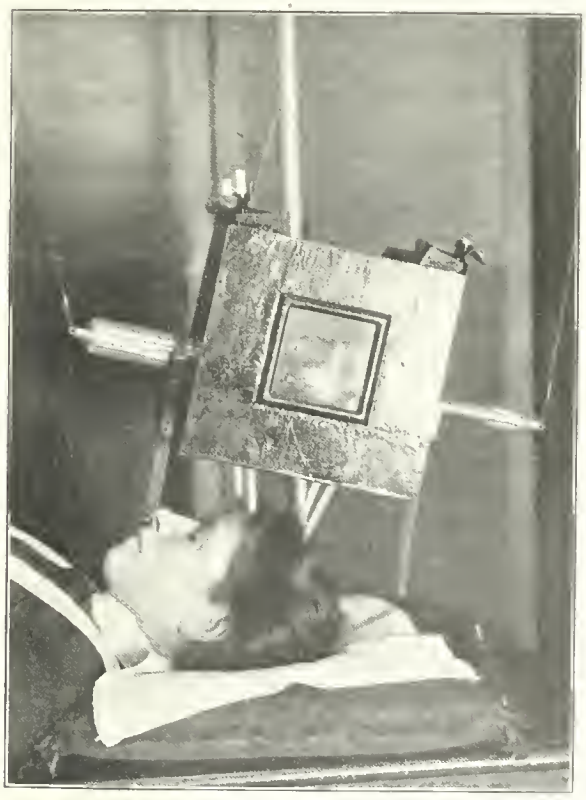

Fig. 16.—Showing tube stand and shield fitted with the wooden pegs for the purpose of holding the head steady.

marked at "skin distance" than at "half distance," and these light brown shades are more easily estimated than are the deeper orange tints. The original dose of 5 H was estimated with the pastille at "half distance," so that when the "skin distance" is

employed the color change in the pastille will be four times less than at "half distance." In other words, when the pastille is placed on the scalp the dose must be multiplied by four. Therefore, the epilating dose at "skin distance" will be $1\frac{1}{4}$ H.

Fig. 17.—Permanent alopecia, atrophy, and teleangiectasia following an erythema as the result of the divided-dose method.

As a matter of fact $\frac{3}{4}$ H to 1 H will usually suffice, and $1\frac{1}{4}$ H is the maximum. If this is exceeded, permanent alopecia is likely to result. The maximum dose will produce a complete depilation, but experience has shown that if most of the hair falls out the result will be perfectly satisfactory, so that a dose of 1 H at "skin distance" will usually suffice for all practical purposes. When employing the "skin distance" the distance between the scalp and anode of the tube is a matter of little moment so long as it is not too close and the same distance is employed for each of the five exposures. A working distance of $6\frac{1}{2}$ inches has been found satisfactory.

The age of the patient makes no difference if the head can be kept quiet during the exposures. For this purpose a shield, fitted with pegs made of soft wood, may be used, as shown in Fig. 16. The pegs must be made of very soft wood, so as not to act as a filter to the ray and should be of a length that will fix the anode at the proper distance from the scalp.

To recapitulate, the essential points in the technique are briefly as follows:

1. Cut the hair short. Indicate points A, B, C, D, and E with a skin pencil. Be certain that the points are exactly five inches apart. Draw lines between the various points as indicated in the illustrations.

2. Apply an epilating dose (H 1 at skin distance, B 9 or 10) to each of the five points. Apply protection only to the face, ears, and neck. The vertical rays are aimed directly at the point under treatment and each exposure must be at right angles to the other exposures.

3. Measure the quantity accurately with a reliable radiometer. The quality must be estimated by means of some reliable penetrometer, such as the Benoist instrument, together with indirect methods such as the milliamperemeter, ammeter, etc.

4. The head must not move very much during the exposure. Absolute immobility is desirable.

This intensive method of treating ringworm of the scalp is scientific and accurate, but on account of the delicate technique it can be employed only by trained radiotherapeutists.

The hair falls out at the end of about three weeks and starts to regrow in about three months. It is essential that no irritating applications be applied to the scalp for two weeks prior to the treatment. As a matter of fact, if chrysarobin, tar, or iodine has been applied, it is better to await the lapse of four weeks. Subsequent to the treatment such chemicals as iodine, tar, and chrysarobin are prohibited. It is preferable to allow no application for about a month, at which time a 5 per cent. ointment of sulphur or ammoniated mercury or some other mild antiparasitic agent may be employed. While the hair is falling the child should wear a linen cap which, with the fallen hair, can be destroyed, so as to protect other children.

Sometimes, a week or two after the treatment, all the patches of ringworm become erythematous and even painful. This is no indication of an error of technique and should not cause alarm. Also, occasionally, a transitory erythema may be noticed a day or two after the treatment. This is an "electrical" erythema and will have no bearing upon the end result. On the other hand, a true radiodermatitis indicates an error in technique and may be followed by more or less permanent alopecia. Fortunately, however, with the modern technique and a skillful operator, such an undesirable occurrence is rare, indeed. Not infrequently, a few hours after the treatment, the child may feel indisposed, but this disappears in a day or two.

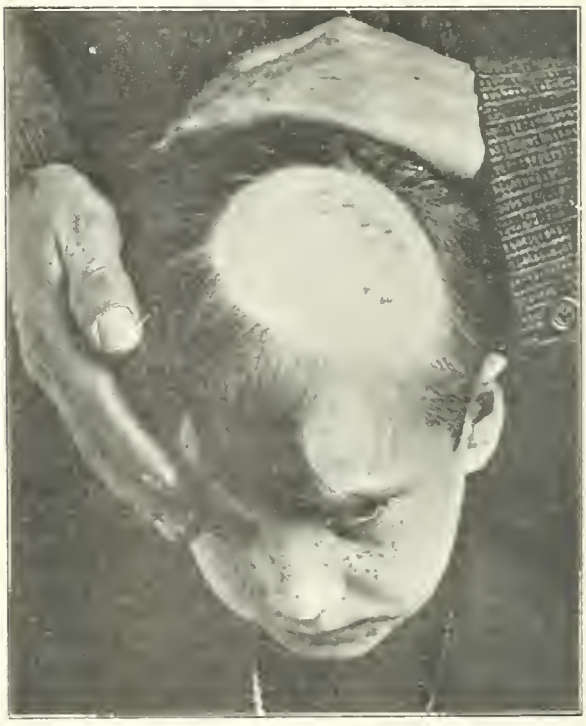

Fig. 18.—Local depilation as a result of a single treatment in a case where the lesions were limited to a small area. In this instance the remainder of the scalp remained unaffected and the result was satisfactory.

In Dr. Fordyce's clinic, Drs. Steinke and Scheer have been treating several cases each week for the past two years and there has not been a single un-

toward result, and this is in accord with the findings in the European clinics. One of us (MacKee) has been employing the intensive method for over eight years, with only two bad results. In one instance, a girl of eight, the hair failed to regrow

Fig. 19.—The areas where the growth of hair is most vigorous are areas in which depilation was provoked on two occasions.

in one area. This was due to the faulty construction of a tube in association with the half-distance method. The same error could not happen with the present technique. The other case was that of a baby where the regrowth of hair was sparse in two areas the size of a silver dollar. This was the result of an erythema following the use of iodine within a short time after the treatment.

In the early days of the intensive treatment of ringworm of the scalp accidents were plentiful, but experience, reliable apparatus, and skill in following out a technique have all combined to make the method reliable and practical (Fig. 17). We will state, too, that there has never been an injury to the brain or to the general system. Not infrequently the new growth of hair will be a little lighter or a trifle darker in shade. Again, the new hair may be curly, while the former hair was straight, and vice-versa.

It is not always necessary to depilate the entire scalp. If there are only one or two lesions, the regions occupied by these lesions may be treated, but when the diseased hair falls out it must not be allowed to infect healthy portions of the scalp. Fig. 18 represents a case of tinea tonsurans where there were three or four lesions in an area about the size of an adult palm. The remainder of the scalp was unaffected. A local defluvium was produced by a single treatment as shown in the photograph. The treatment resulted in a cure.

Inasmuch as we estimate the quantity by direct measurement, the element of time does not enter into our calculations. With the apparatus and technique in use at present an epilating dose can be administered in a few seconds or in a few minutes. We usually give the dose in three minutes, making a total exposure, for the five areas, of fifteen minutes. Considerable time is lost in mapping out the areas on the scalp, arranging the position, obtaining the confidence of the child, etc., so that it usually requires about an hour to complete the treatment in one case. It is not necessary to expose all the areas at one time. If one desires to do so one area may be treated each day, five consecutive days being utilized for the complete procedure.

Relapses occur occasionally, making it necessary to depilate a second time. In such instances it is usual to allow a period of from six to twelve months to elapse. We doubt, however, if this long interval is essential. We have had numerous cases where we have depilated a single small area and later the entire scalp has become infected, necessitating a universal defluvium. In these instances we waited until the hair began to grow in the original patch, about three or four months, and then depilated the entire scalp. To our surprise the hair reappeared in the original area before it began to grow over the remaining portions of the scalp (Fig. 19). However, it is probably wise to allow an interval of at least six months so as to avoid any possibility of an accumulative effect, especially if the hair is not growing vigorously. In several instances, where the entire scalp was depilated by the intensive method, we noticed that the hair grew more rapidly in the areas previously affected by the disease than in the normal scalp.

The question of idiosyncrasy undoubtedly occurs to the reader. We cannot deny that a true idiosyncrasy is a possibility, but it must be extremely uncommon. We have personally never detected a single instance of true idiosyncrasy in connection with the scalp. Thousands of cases have been successfully treated in Europe and our foreign colleagues ascribe the comparatively few bad results to faulty technique rather than to idiosyncrasy.

Although, in the hands of experienced radiologists, accidents are extremely rare, yet it cannot be said that the *x*-ray treatment of tinea tonsurans is entirely devoid of danger. On the other hand there is no question but that if properly conducted it is the best means that we have at the present moment for combating ringworm of the scalp; and we should here include the hitherto practically incurable disease, favus. Here, however, the crusts must be removed before the application of the

Fig. 20.—Favus, showing the thick crusts which must be removed before applying the *x*-ray.

x-ray, because they absorb the ray, thereby acting as filters, and interfere with the accuracy of the dose (Fig. 20). In this connection, however, we desire to call attention to some recent work conducted by Strickler of Philadelphia with the vac-

cine treatment of tinea tonsurans. He succeeded in curing several cases by this method and it is quite possible that the future will see this procedure supersede the *x*-ray treatment of ringworm of the scalp. For those who are interested, Strickler's article was published in the *Journal of Cutaneous Diseases* for March, 1915.

For those who desire to study the technical details of *x*-ray measurement and, also, to obtain additional information relative to the intensive *x*-ray treatment of tinea tonsurans, we append an incomplete bibliography of useful articles in the English language.

Anesthetics and Coagulation Time of the Blood.—W. L. Mendenhall finds that coagulation time is little altered by chloral hydrate unless it is normally short, in which case this time is prolonged. Chloroform has the same effect. This result is probably caused by the disturbance and consequent interaction between two or more organs which are important in the coagulation process; probably the liver (intestine?) and the suprarenal glands. Coagulation processes are hastened by ether anesthesia, which effect is exerted wholly through the action of ether upon the suprarenal glands.—*American Journal of Physiology.*

THE PEACE AND WAR FOOTING OF ALCOHOL.

By EDWARD HUNTINGTON WILLIAMS, M.D.,

LOS ANGELES, CAL.

FORMERLY ASSOCIATE PROFESSOR OF PATHOLOGY IN THE STATE UNIVERSITY OF IOWA, AND PHYSICIAN IN THE NEW YORK STATE HOSPITAL SERVICE; MEMBER OF THE BRITISH SOCIETY FOR THE STUDY OF INEBRIETY, ETC.

THE physiological and pathological effects of alcohol have probably been more thoroughly investigated, contended over, and disagreed about during the last quarter of a century than almost any other subject. Physiologists and chemists have studied the action of alcohol upon normal organs; pathologists and clinicians have investigated its morbid and therapeutic effects; and its moral and economic significance have been subjects of contention that rival the religious and metaphysical discussions of the Middle Ages.

Yet the net results of this active fermentation—that is, the actual facts about which all investigators agree absolutely—may be summed up in the simple statement that excessive quantities of alcohol are harmful. A similar statement may be made about at least a hundred other substances. Nevertheless, a certain number of positive discoveries have been made, and a somewhat larger number of fallacious pathological and therapeutic bubbles have been definitely pricked.

Events in Europe during the last few months have added material for digestion. Thus the edicts of certain governments against the sale and manufacture of distilled liquors emphasize the belief among physicians that the effects of concentrated beverages are especially harmful. But perhaps the most disconcerting, as well as one of the most important events in recent years, in its bearing on the problem, was the discovery that paresis is caused by syphilis, not by alcohol, as widely believed heretofore. This discovery, although intrinsically important, is even more so in its implication. This implication is, obviously, that there may be other pathological conditions where the verdict against alcohol seems quite as justifiable as in the case of paresis, but in which the decision may be reversed at any time by the higher court of scientific investigators. Indeed, several similar decisions have been handed down recently. But although such decisions tend to clarify the atmosphere in certain regions, the general effect is somewhat disconcerting.

Positive and Negative Findings of the Court.—The verdict against large quantities of alcohol as a poison is confirmed beyond question. But the cases involving the poisonous effects of small doses is more complicated. Thus, we may measure the action of large doses of alcohol by a series of definite effects, whereas the results of persistent small doses can seldom be measured by specific and uniform pathological conditions. In this respect, then, alcohol differs from most substances officially rated as poisons.

There is, of course, a great difference in the effects of a large dose of any poison, and small amounts of the same poison distributed over a long period. Lead, arsenic, mercury, and opium offer examples of this. But even slow poisoning by these substances can be measured in pathological terms with reasonable accuracy. Such is not the case with alcohol, however. What particular organ of the alcoholic will succumb, or whether any organ will be demonstrably affected at all, is entirely a matter

for speculation. The drunkard may develop nephritis, or cirrhosis of the liver, or multiple neuritis, or pay one of a dozen other seeming penalties. Yet any of these conditions may be produced by some agency other than alcohol, since the total abstainer is not immune. Indeed, exhaustive investigations raise strong doubt in many cases where formerly the circumstantial evidence was regarded as convincing.

The effect produced upon the blood by alcohol is a case in point. It has been asserted repeatedly that alcohol causes the blood corpuscles to shrink, "lose their round form, and become ragged," as stated by Henry Berg. The recent experiments of Jaillet, Evelin, and Quensel, however, absolutely refute this, and Quensel makes the definite assertion that, "in investigations made upon human beings who have misused alcohol, no morphological changes in the blood have been proven."

The effect produced upon the normal liver by alcohol seems entirely enigmatic, although our predecessors confidently stamped cirrhosis as "drunkard's liver." Recent, and more scientific investigations, however, fail to find complete justification for this stigma. Thus Baumgarten found cirrhosis of the liver in only 6 per cent. of autopsies among hard drinkers, and Fahr found only a trifle over 4 per cent. (13 cases in 309 autopsies). From their investigations it appears that total abstainers suffer from this disease about as frequently as alcoholics.

Investigations of cases among moderate drinkers offers confirmatory evidence. The official statistics of the hospitals in Sweden, for example, show that there were 21 deaths from cirrhosis of the liver annually to 10,000 patients. Considering the character of the cases investigated the evidence seemed sufficiently conclusive to the investigators, who state that, "as a basis for the hypothesis that a moderate use of alcohol may originate the disease, the number of cases is exceedingly small; the number found seem to furnish a direct proof for the incorrectness of such an assumption."

However, these conclusions need not remove the suspicion that the abuse of concentrated alcoholic drinks may be an etiological factor in cirrhosis, even if not a specific cause, although animal experimentation has failed to demonstrate such action. Yet cirrhosis seems to have decreased in recent years, while the per capita consumption of alcohol has steadily increased. Possibly the universal change in diet may be a factor. But Lambert attributes this decrease in the disease to "the more general use of malt liquors," making the obvious implication that concentrated alcoholic drinks may cause the disease, although the lighter beverages do not.

The case against alcohol as the cause of organic heart disease will not stand close scrutiny. Indeed, our knowledge of the toxic action of certain proteins and other nutritive agents makes it fairly certain that, at most, the action is indirect, and of no more importance etiologically than many staple articles of diet. Functionally, the heart is affected by alcohol like other muscles of the body through the central nervous system—that is, the immediate effect on the heart's muscular effort is "to diminish the efficiency of the individual contractions, and the remote effects, to delay the onset of fatigue. Under its influence the muscle contracts less perfectly from the start but continues at this slightly lower level for a longer time, with the result that more work is performed before it becomes exhausted." The clinical value of alcohol, therefore, is well recognized; but there seems to be no evidence to support the contention that even chronic alcoholic abuse produces organic heart changes.

The old conception of alcohol as a direct etiological factor in diseases of the blood vessels, particularly arteriosclerosis, has been recently reversed. The older writers stated positively that alcohol is a direct cause of arteriosclerosis, but recent investigations all tend to refute this. Thus Cabot, reporting on these conditions, states that "only 6 per cent of 283 cases of chronic and excessive alcoholism under 50 years of age showed any evidence of arteriosclerosis." And, "of 45 cases of arteriosclerosis examined by me at the Massachusetts General Hospital, only 13 per cent gave a history of alcoholism." In the opinion of Louis Faugeres Bishop, "pure alcohol well diluted and taken in appropriate quantities with relation to food, probably has no effect" in producing arteriosclerosis. While the investigations of Lancereaux, Duclos, Orth, Schell, and Fahr offer evidence that not only may arteries in pronounced drinkers show an absence of arteriosclerotic changes, but also that arteriosclerosis is not found earlier or to a greater extent in alcoholics than in other persons.

The close relationship between diseases of the heart and blood vessels suggests that the conclusions about alcohol as an etiological factor in nephritis would be practically the same as in the case of the other organs. This appears to be the case. In a comparative series of cases investigated by Lafont, for example, there were 6.3 per cent of cases of nephritis among alcoholics, while in non-alcoholics there were 7.3 per cent. Even where nephritis was present in alcoholics, the etiological factor was so doubtful that Lafont stated, "we cannot assert that nephritis in alcoholics is of alcoholic origin." In Fahr's series, chronic nephritis caused the death of but eight cases, and was less commonly noted than among the non-alcoholics. And Hultgren, in a long series of investigations, found no evidence of nephritis in 85 per cent of alcoholic cases, and concludes that the tissues eliminating alcohol, such as the kidney, suffer less from its effects.

Probably the most exhaustive investigation of this question has been made recently in Leipzig, with the net result that "no specially prominent influence of alcoholism was established over that of other substances." In this investigation the cases were divided into age groups, and although the age class between twenty-five and thirty-four showed a slight difference unfavorable to the alcoholic, the difference was so slight that the general conclusion was not affected in view of the showing in the other classes. In this connection it should be borne in mind that the subjects investigated were not merely habitual drinkers, but confirmed alcoholics.

Our knowledge of the effects of alcohol upon the gastrointestinal tract is apparently somewhat more definite, or at least, positive, in character, than in the case of most of the important organs. Our present knowledge is summarized in the succinct statement that "gastric digestion is not materially affected by moderate amounts of beer and wine of low alcoholic content, and they may even promote digestion, but brandy and whiskey, containing about 50 per cent of alcohol, interrupt digestion when taken in sufficient amount, and digestion is not resumed until the concentration of the alcohol is reduced sufficiently through absorption or diluted with the

gastric contents." It is also accepted as a physiological fact that small amounts of alcohol are absorbed rapidly from the gastrointestinal canal, and favor the absorption of other substances, while larger amounts of concentrated liquors produce the opposite effect, with resulting disorders.

The objective effects of alcohol upon the central nervous system are so definite and characteristic that an analysis of these effects would appear relatively simple, and demonstrable by pathological findings. But such is not the case, particularly as regards the effects of small quantities of alcohol. Thus, Binz and his followers, hold that alcohol stimulates the nervous system; Schmiedeberg maintains that its action is wholly depressant; and pathologists assert that, organically at least, small quantities of alcohol produce no effects whatever. Moreover, there is no uniformity in organic changes, even in cases of marked alcoholic abuse. In delirium tremens, for example, such investigators as Bonhöffer, Trommer, and Lambert find no specific pathology by microscopic examination.

On the other hand there are certain fairly constant organic changes, such as hyperemia of the membranes, cloudy thickening and adhesions of the pia, edema, minute hemorrhages, and perhaps actual degeneration of the cells and fibers, which are often the concomitants of inebriety. And although it may be fairly pointed out that these changes are also produced by other toxic substances, and that none of these conditions are constant even in alcoholics, we are justified in the belief that these changes may be produced by alcoholism.

It appears, therefore, that the demonstrable organic changes produced by excessive quantities of alcohol are confined almost exclusively to the nervous system, and the alimentary tract. Any definite organic changes in the blood, bloodvessels, heart, liver, kidneys, and muscular system, have not been established. So far as we have been able to demonstrate, specific changes are not produced.

Effects Produced Upon Pathological Structures.—The moment we consider the effects of alcohol upon pathological structures, however, particularly the effects of concentrated liquors, we find ourselves on firmer ground. It is generally accepted without reservation that any considerable quantity of ardent spirits is harmful in cases of heart disease, nephritis, arteriosclerosis, diabetes, and many other pathological conditions. The fact that other substances, such as tea, coffee, tobacco, and certain foods also act detrimentally in these conditions, indicates that the action of alcohol is not that of a selective poison, but rather one of a group of substances whose action upon pathological structures differs somewhat from the physiological effects.

Similarly, we have a striking example of the effects of alcohol upon abnormal structures in the alcoholic insanities. Probably alcohol acts in these cases as the spark for igniting the mental powder mine, which results in disrupted mentality, with characteristic manifestations. Perhaps the explosion would have occurred without this particular spark, for it is the consensus of opinion among psychiatrists that the train itself was already laid. In short, that the person in whom the use, or even abuse, of alcohol produces insanity is mentally unstable, and conversely, the person of normal mental stability seldom, if ever, develops an alcoholic psychosis.

Moreover, it seems pretty clearly established that, even in cases of unstable mental equilibrium which develop into alcoholic insanity as the immediate result of alcoholic abuses, the kind as well as the quantity of beverage consumed is an important factor. An overwhelmingly large proportion of persons who develop alcoholic pyschoses in America are drinkers of whiskey, or some corresponding ardent spirit, whereas this condition is seldom seen in beer and wine drinkers. This difference is so pronounced that the drinking habits of the different nationalities may be pretty accurately measured by the heterogeneous asylum populations in this country. Thus we find the highest percentage of alcohol psychoses among the whiskey drinkers who come from Western Europe, while the wine and beer drinking races of central and southern Europe show a distinctly lower percentage, in some instances only about one-fourth as many per capita.

There are undoubtedly other factors besides the kind of liquor, which must be considered in explaining this difference in race-susceptibility to alcohol. But it is evident that quantity of alcoholic content in the beverage, and quality of mental endowment, are highly important elements.

The deleterious effects of alcohol in certain pathological conditions suggest its value as a therapeutic agent in others. This value is, of course, recognized universally among clinicians. Yet therapeutically, as well as physiologically and pathologically, alcohol presents some curious paradoxes even in the course of the same disease. Take the case of diabetes, for example. Apparently alcohol plays no direct part in the etiology of this disease. But once the disease has developed, the harmful effects of liquors having a high alcohol content, such as whiskey or brandy, is unquestioned. Yet there are phases of diabetes in which a veritable drenching of the system with whiskey lifts the patient over an abyssmal chasm. At these critical periods, von Noorden "advises no food, but large quantities of whiskey. * * * He calls these days 'alcohol days,' and says it is astonishing how well large quantities are borne even when the patient is not accustomed to them. It is followed by a large reduction of ketonuria, and the general condition of the patient is greatly improved."

This, and kindred clinical experiences, simply emphasize the complexities of the alcohol problem from a medical standpoint. In therapeutic effects, as in physiological and pathological manifestations, our knowledge is still largely empirical, which, from a strictly scientific point of view, is rather haphazard, and peculiarly dependent upon personal prejudice.

The War Status of Alcohol.—A leaf from the book of the great war shows the status of alcohol from a European standpoint. We see the warring nations issuing sweeping edicts against the sale and manufacture of distilled liquors, thus emphasizing the deleterious effects of concentrated alcoholics as a social factor, and presenting a unique feature of modern warfare. But following this we are given abundant evidence of the belief in the therapeutic value of alcohol by the action of these same governments. England, urging temperance upon her soldiers and civilians, sends liquor to the trenches and hospitals in hundred thousand gallon lots. France, having interdicted the use of absinthe, increased the daily wine ration of the soldiers. Germany first closed all bars until mobilization was effected, then lifted the edict against beer, and encouraged its gift to armies and hospitals. And Russia expressed the universal sentiment against the use of concen-

trated liquors by a sweeping and permanent (it is to be hoped) edict against the deadly vodka.*

This action of the great European powers suggests an attitude toward alcohol legislation that is wholly novel, at least in America. The action was discriminatory against a certain class of alcoholics that is entirely justified by clinical experience. But it is a curious commentary on American legislative acumen that this rational first step to abolish alcoholism should be taken in countries where an appreciation of the urgency of some reform is of recent origin, rather than in our own country where the quest for some practical legislative control has been acutely active for years.

If we consider war as a pathological condition, the action of these belligerent governments in regard to alcohol may be considered as a therapeutic measure, confirming the belief that alcohol is a useful remedy, even though a harmful economic factor. But war is only pathological from a political standpoint. Physiologically it is precisely the reverse, for the effectiveness of an army is dependent upon the physical efficiency of its units. When, therefore, the European governments encourage the use of a certain type of beverage among these units, and forbid others, it is not for the purpose of correcting a pathological condition, but to enhance a physiological one. In short, the beverages are not given as medicine, but as nourishment.

The use of alcohol in the military hospitals seems to accord with the practices in civil hospitals. Ardent spirits have lost ground in popularity, and the lighter beverages distinctly favored by the military surgeons, this attitude presenting a striking contrast to the attitude of the surgeons in former wars. In our Civil War, for example, whiskey and brandy were used in tremendous quantities, wine to some extent, and malted beverages scarcely at all. In the European war this order of precedence seems to be reversed.

Thus the tendency in war, like the tendency in civil life, is to condemn, or restrict, the use of ardent spirits, therapeutically and generally. There is a lesson in this quite outside the field of medicine that may well be taken to heart.

Exchange Building.

*According to the *British Medical Journal*, 2½ ounces of rum are issued to each man in the British Army twice a week. For men in the trenches, this allowance is increased to 3 ounces twice a week under ordinary weather conditions, and to 2½ ounces daily in very bad weather, making a minimum of 5 ounces a week and a maximum of 17½ ounces. The regular ration of 2½ ounces is estimated to contain 25.5 grams of alcohol. The French soldier receives daily 50 grams of rum containing 20 grams of alcohol. The German soldier is allowed 1,793 grams of beer and 20 grams of brandy a day. The beer, which is of course the ordinary lager variety, has a low alcohol content of only about 3.5 per cent., but this quantity would amount to a total of 70.7 grams of actual alcohol a day. Austrian soldiers receive each day 0.5 liter of wine, equivalent to 40 grams of alcohol.

Intestinal Obstruction Caused by Ascarides.—Y. Takaki reports a case of this condition in a child aged three years in whom a diagnosis of intussusception had been made because of the existence of a long tumor running across the right side of the abdomen just above the umbilicus. Doubt as to the diagnosis was raised by the detection of a second tumor which was small and round and was situated in the right iliac fossa. There was considerable abdominal pain associated with a moderate degree of distention. The patient vomited ascarides at various times. Following the administration of santonin, a large number of the worms passed with the feces and the tumors disappeared.—*Sei-I-Kwai Medical Journal.*

TUBERCULOSIS IN CHILDREN.*

By WILLIAM W. RIHA, M.D.,

Bayonne, N. J.

Attending Physician in the Hudson County Tuberculosis Clinics.

Human history may be divided into several more or less well-defined eras. Antiquity, as portrayed in mythology, represents the era of the warrior. In those days, as Plato subsequently taught and all Athens believed, man existed for the benefit of the State, and man's "summum bonum" consisted in the sacrifice of self for the glory of Greece. Later we come to the era in which some of the world's best philosophy and poetry received the stamp of immortality, and during which majestic monuments, temples, and triumphal arches were built; during which wealth was pouring into the Eternal City from all the corners of the earth, and during which a new religion, destined to be world-wide, came into being. That was the era of philosophy, poetry, architecture, and sculpture. Following the era of intellectual triumph and material prosperity, there came an era of asceticism and mysticism, the days of the hermit and the monk. The intellect of man fell asleep and the Dark Ages had come. The darkness was like ebony and the night long; but dawn came and ushered in the era of the Renaissance, when man was aroused from his mental inertia and the intellect came into its own again. And as we travel thus through subsequent centuries to our own day and generation, we ask ourselves the question, "What characterizes this era in which we are living?" Some may say that this is the era of industry and commerce; or the era of great wealth; or the era of discoveries and inventions; or the era of scientific achievements. All these characterize our era, but over and above all these, *this is the era of the child.* The efforts of the disciples of eugenics; the workers interested in the conservation of child life, improving the sanitation of our factories, regulating the working hours of children, inspecting the dairies and their products, opening milk-stations for the babies; the activities of the Little Mothers' League; education through the distribution of pamphlets fighting under the slogan "It is not the babies born but the babies saved that count"; the establishment of Fresh-Air Camps, the widows' pensions, clinics for the study of child tuberculosis, the systematic medical school-inspection, the recognition of the importance of prenatal care, and the recent establishment of the Children's Bureau by our government and the free distribution of its literature, all these bear witness to the fact that the child has at last inherited its birthright. To say it again, this is the era of the child.

You have heard it said that the child is the father to the man; and that as the twig is bent so will the tree grow. The child is like clay in the hands of the potter; we can mould it as we will. Bad habits are just as readily acquired as good ones. And thousands of mothers are this day making bricks in Egypt because of the pernicious habits they themselves taught their children. How important is it, therefore, that our twigs grow straight, in fertile soil and wholesome atmosphere, for in this era of the child the weaklings have no chance and only the strong become efficient.

* Read at the meeting of the Association of Attending Physicians to the Hudson County Tuberculosis Clinics, May 10, 1915.

This brings us to the subject of prophylaxis in infancy and childhood. It has been said that it is more blessed to give than to receive. I would like to paraphrase this truism into terms of medicine and say that it is more blessed to prevent than to cure. Combating the ignorance of the parent will prove more arduous than combating the disease. When we appreciate the fact that we possess the magic word—the open-sesame—that brings before our eyes enormous wealth of knowledge, when we realize that the unanswered mysteries of other ages are now as understandable as the alphabet, what a sad commentary on our civilization is it that there are many humans among us who in their mental equipment are still back somewhere in the days of Hildebrand. Where is the man who said that ignorance is bliss? What is blissful about the mother who moistens her nipple with her tuberculous sputum in order to facilitate the introduction of her nipple into the mouth of her nursling? Can door-crevices stuffed with rags and window-crevices passe-partouted lead to bliss? Can a child living in overheated rooms and raised like a hot-house plant or vegetable bring bliss? The character of the odor that greets one's nostrils on entering a home thus hermetically sealed challenges description. Hebraic tradition tells us of the nautical experiences of Mr. and Mrs. Noah and relatives who, together with the greatest menagerie ever assembled before or since, lived, during a certain stormy season, in an ark the *only* window of which remained closed for 40 days and nights. How the sailors could stand it will ever remain a mystery to me. The crusts of dirt that we find on not a few of our patients bespeak a shiftless habit that is incompatible with the results we seek to attain. Cleanliness has ever been next to godliness; and as someone has said, "a healthy skin is the best undergarment ever invented." But one cannot get blood from a stone; and it is just as impossible to have cleanliness without a bathtub. Therefore we should advocate the erection of municipal bathhouses in the congested districts of our cities. A sin against hygiene that is common to all classes is that of overdressing. The binder, woolen-shirt, petticoat, top-coat, stockings, booties, and cap, and over them all the mother's heavy shawl, or among the rich a fur sleeping-bag, may constitute the proper wearing apparel in the land of the penguin and the bear, but never in the temperate zone. Overcrowding is another condition that causes tubercle bacilli to frolic gleefully in pulmonary tissue. Before the days of urban life, when man was enjoying the primitive privileges that were his in the Valley of the Euphrates, infectious diseases were rare and man was as disease-free as the game he hunted. But with the advent of large industries and the multiplication of man's necessities and the added demands made upon him by society, man ceased to live for himself only and found himself with others of his fellows herding into cities. As someone has said, "tuberculosis is a disease of man who lives in houses and of cattle that live in stalls." Tuberculosis is a disease of crowds.

Fresh air is nature's true panacea, given gratis to all mankind. In these days when children frequent the movies, and dancing is taught to develop gracefulness, we may justly wonder where are the good old days when children rolled the hoop, skipped rope, and played London-bridge-is-falling-down, when children sported in the open air and were rewarded with healthy lungs and rich, red corpuscles. A healthier and happier youngster never lived than our poet's "barefoot boy with cheek of tan," whose red lips were "kissed by strawberries on the hill," and not by doting parents and misguided relatives. Open-air schools should be advocated for both therapy and prophylaxis. In our large cities there are open-air schools for *non*-tuberculous pupils. These schools report that the children eat better, play better, sleep better, look better, and study better than students in the ordinary type of school. The reason is obvious. The question of food is an important one. When a poor child has coffee and bread for breakfast, and tea and crackers for luncheon, and a large plate of soup (with the emphasis on the "large") and a piece of dry, flavorless beef besmeared with mustard or some other useless condiment for dinner, is it any wonder that in this wasting disease the tubercle bacilli are coaxed out from their dugouts and a most serious conflict ensues? This being so, our public schools should give a light, nutritious luncheon during the morning and afternoon recess periods to the tuberculous, and the anemic, and the underfed.

If ever an ounce of prevention was worth a pound of cure, it is worth that in our tuberculosis work. *The proper individual to begin with is the newly-born.* Indeed, it is well to begin with the fetus by instructing the mother in the hygiene of pregnancy and by explaining to her the value of certain pathological danger signals. Two centuries before the Christian era, the Emperor of China caused a collosal wall to be built along the entire length of the northern frontier of his country, in order to keep the Mongolian Tartars from invading his kingdom. But the formidable wall of Chi-hwang-ti accomplished nothing, for the Tartars invaded the country and spread destruction everywhere. In our tuberculosis work we, too, are endeavoring to build a wall—a wall of resistance—against one of the worst bands of marauders known to man—the tubercle bacilli. But this great wall will accomplish nothing, its masonry will crumble to the earth, and our efforts will be for naught if we delay our constructive work until the marauders have become too powerful for us. What has made malaria an infrequent disease? Surely not the tons of quinine that had been used, but the tons of dirt that had been dumped over the marsh lands. And so, what will it profit us in our tuberculosis propaganda if we arrest tuberculous lesions in the adult and fail to attack the mischief at its source? You have heard of the two Scotchmen, who, all breathless, reached the railroad station just as their train was pulling out. Malcolm turned to his comrade and said, "Donald, tha did na run fast enough." Whereupon Donald replied, "Ah did run fast enough, but ah didna start soon enough." And so in our tuberculosis work we may be displaying energy and enthusiasm enough, we may "run fast enough," but if we fail to begin with the infant then we "didna start soon enough," and, like the Scotchman in our story, we will miss something—in our case an opportunity to use one of the masterstrokes in prophylaxis. For to guard against the spread of tuberculosis we must prevent contact with individuals suffering from the disease.

Hess of New York says, "Unless the infection of young children is adequately guarded against, what basis is there for any hope of eradicating the disease in succeeding generations?" And he cuts the Gordian knot by advocating the establishment of tuberculosis preventoriums for infants. Fishberg

of Bellevue, writing in the *Archives of Pediatrics*, presents the following startling revelation: Among 588 apparently healthy children of *non*-tuberculous parentage, 52.72 per cent. gave a positive reaction to tuberculin:

Of those from 1- 2 years, 33% reacted positively,
Of those from 3- 4 years, 41% reacted positively,
Of those from 5- 6 years, 50% reacted positively,
Of those from 7-10 years, 64% reacted positively,
Of those from 11-14 years, 69% reacted positively,
and at 14 years, 75% reacted.

And according to Hamberger, 90 per cent. of all children become infected before reaching the twelfth year of life.

This leads us to the study of *infection*. It is no longer claimed that the bovine and human tubercle bacilli are identical. Baumgarten claims that at the present time the discussion centers about the point as to whether there are two different and separate species, or one species descended from a common ancestor, that has in the course of time acclimated itself in man and cattle and subsequently developed two different varieties with characteristic differences in morphology, in cultural peculiarities, and in virulence for rabbits. In the English translation of Pfaundler and Schlossman's voluminous work on Diseases of Children, Schlossman writes, "In tuberculous individuals the bovine type is found relatively seldom, and as yet *only in children under eight ears of age*." Of course, the greatest danger of infection by the bovine type lies in the use of milk from tuberculous cows and from dairy products such as cream, butter, cheese, and curds. Those of you who are familiar with the milking process in vogue in the ordinary unsanitary dairy, and have noticed the total absence of milk-cooling facilities, and have observed the milk can with its contents standing for hours in the sun, during which time millions of microorganisms were warmed into life, will agree with me that the infant using such milk has the sword of Damocles hanging over it. Reports from our laboratories tell us that tubercle bacilli are not killed by pasteurization. Boiling of the milk will be our best preventive. A. Philip Mitchell of Edinburgh found that in 90 per cent. of his cases of tuberculosis of the cervical glands infection was due to the bovine bacillus, and that 84 per cent. of these children had since birth been fed raw cow's milk.

Before discussing *the portals of entry*, it is well to heed the advice of Simon, and differentiate between an "infection" and an "infectious disease." An infection is the invasion of the body by a microorganism, while an infectious disease is the symptomatic, clinical manifestation of such an invasion. Four portals of infection are recognized: (1) the placentogenous form, (2) the dermatogenous, (3) the enterogenous, and (4) the bronchogenous. In the placentogenous form, infection of the fetus is said to occur through the placental blood circulation. It was Schmorl who published the first proof of the passage of tubercle bacilli from the maternal blood to the placenta, and from it into the fetal liver. Although there are several cases on record to prove placentogenous infection, and reported by men who can speak *ex cathedra*, this form of infection is, however, very rare. Furthermore, infection may occur through the aspiration of infected amniotic fluid. Ghon in Europe and Wollstein in America have shown that the bronchi become infected, when the infection extends to the lymph nodes at the hilum and to the lungs. Another investigator claims, through his experiments on animals, that tubercle bacilli can at the same time fecundate and infect an ovum. The dermatogenous form, like the form just mentioned, is very infrequent. Primary infection of the skin in a baby two months old has been reported, the child having been bitten on the cheek by a tuberculous nurse. Infection of the skin occurred and necropsy showed pulmonary involvement with cavity formation. The enterogenous form may be dismissed by giving the testimony of von Pirquet, who says that no characteristic lesion of primary intestinal tuberculosis has been found. But Osler mentions a series of 3104 cases of tuberculosis in children, with fifteen cases of primary intestinal tuberculosis. This leaves us the bronchogenous form, mentioned last in order to get the most emphasis. Von Pirquet has found that in 95 per cent. of all cases of tuberculosis, infection took place through inhalation. Baumgarten says that the tubercle bacillus has the property of latency, infection having occurred in infancy and the bacillus lying dormant for weeks, months, or even years. There is then a general mobilization of the fighting forces of the body, trenches are built before the enemy, our heaviest artillery holds the vantage ground and the forward movements of the foe adequately guarded against. But when the general is out-maneuvered, when there comes to pass a most successful flanking movement by a new enemy just arrived—let us call him "measles" or "pertussis"—the trenches are destroyed, the mobilized forces are routed, and when the smoke of battle lifts we stand appalled at the extent of the destruction that was wrought.

Rach, von Pirquet's assistant, has been able to isolate six types of pulmonary tuberculosis in children, arriving at this conclusion through his radiographic studies. These six types are: (1) Ghon's primary focus; (2) intumescent tuberculosis of bronchial glands; (3) intrapulmonary hilum tuberculosis; (4) miliary tuberculosis; (5) Nursling's phthisis, and (6) apex tuberculosis. For this classification I am indebted to Dr. Michael, who presents an exhaustive résumé of the subject in the *American Journal of Diseases of Children*. *Ghon's primary lesion* is a sharply defined bean-sized shadow found isolated and free in the pulmonary field, and at the same time showing an enlargement of the glands draining this area. Ghon's lesion may appear anywhere in the lung. *Intumescent tuberculosis of bronchial glands* produces a shadow to the right of the median shadow, the convexity extending upward, then running parallel to the median shadow, finally turning backward and again joining the median shadow. Their enlargement may produce pressure on neighboring structures. The glands become infected from a primary focus in the lungs as a result of inhalation, periadenitis with adhesions follows, the glands become attached to a neighboring bronchiole two or more tubercles coalesce, softening and caseation occur, the cheesy matter breaks through the wall of the bronchiole and is discharged into its lumen. This then may be aspirated into the finer bronchioles and eventuate in a caseous bronchopneumonia. *Intrapulmonary hilum tuberculosis* consists of caseated intrapulmonary glands in the vicinity of the hilum, and of caseated areas extending laterally from the hilum in streaks. These streaks are thickest in the region of the diseased glands, and become thinner and thinner as the periphery of the lung is approached.

In *miliary tuberculosis* the *x*-ray will give the characteristic picture weeks before clinical symptoms appear. In *nursling's phthisis* the *x*-ray shows numerous areas of caseous pneumonia with cavity formation. *Apical phthisis* is the same as seen in adults. It may begin as early as the seventh year.

We come now to the subject of *diagnosis*. Lees, writing in the *British Medical Journal*, says that accurate and careful percussion in the diagnosis of pulmonary diseases in children takes precedence over any other form of investigation. Goldschneider suggests a form of percussion which he uses in percussing the chests of infants. The finger is placed vertically on the infant's chest, and the distal phalanx percussed. The tracheobronchial lymphglands constitute the most common location of tuberculosis in children. I shall therefore limit my paper to this form. The two chief symptoms on which a diagnosis of enlarged glands is made are *cough* and *dyspnea*. The cough is brassy and nonproductive, and becomes more pronounced after an injection of tuberculin. The dyspnea is inspiratory and expiratory, the point of importance being that in spite of severe dyspnea the voice is clear, proving that the obstruction is below the larynx in the lower air passages. The danger signs—the "stop, look, listen"—that are suggestive of glandular involvement, are: (1) cough, (2) dyspnea, (3) failure to gain weight, (4) visible veins over chest, neck, and temples, (5) palpable glands, (6) *x*-ray findings, (7) reaction to tuberculin, (8) temperature changes, (9) history of exposure to infection. And in addition, I have gleaned the following from recent literature, and offer it to you for what it may be worth: (1) the lymphatic diathesis (the pasty look, swollen lips, thin nose, rhagades, swelling of lymphatic tissue, inflammation of the cornea, phlyctenular conjunctivitis, and catarrh of the upper air passages; (2) changes in the percussion note over the sternum at the level of the second or third rib; (3) relative lymphocytosis which can be increased by an injection of tuberculin; (4) d'Espine's sign; this consists of bronchophony over the spinous processes at a lower level than normal—at the seventh cervical in young children, at the first dorsal in those eight years old, and at the second dorsal in those twelve years old; (5) dullness on percussion in the right interscapular region; there exists normally on each side of the spine and extending for one inch from the midline and between the first and fifth dorsal vertebræ, an area of slightly impaired resonance elicited by gentle percussion, but which in cases of enlarged glands extends out for two or three inches from the midline and downward to the sixth, seventh, or eighth dorsal spine. Yet over against this mass of research, witness this pessimism of Henoch, who says, "can we diagnose the condition of bronchial glands during life by any definite symptoms? As far as my own experience goes, I must answer the question in the negative in the great majority of the cases. The clinical descriptions that authors give of glandular enlargement have the look of having originated in the study and not at the bedside." Commenting on Henoch's opinion, Clive Riviere says, "the *x*-ray has helped us some at present, but in the main Henoch's opinion still stands."

A word about *tuberculin* which, like the *x*-ray, may help us in diagnosis. In using von Pirquet's test the ordinary method of scarifying may produce a traumatic reaction which causes confusion in the proper interpretation of the reaction. Only the gentlest and mildest scarification should be used. If positive, a red papule will appear in from twenty-four to forty-eight hours, and which, in the course of a few days, will leave a pigmented area similar to the one following Schick's present-day test for diphtheritic immunity. Von Pirquet says that the reaction-area should measure from 10-30 mm. in diameter, and if it measures less than 5 mm. the reaction should be classed as doubtful. If negative, the test should be repeated again in three weeks. Clive Riviere says that the reaction will be negative in tuberculous cachexia, after treatment with tuberculin, and during acute infectious diseases such as measles and scarlet fever. A positive reaction is of little value after school age is reached. The younger the child the more valuable the positive reaction. A new test described by Blumenau is the *plaster test*, which I mention only because of its newness. The skin of the forearm is cleansed with ether, a drop of tuberculin is placed on the flexor surface near the bend of the elbow and covered with a piece of adhesive plaster 3 cm. square. The edge of the plaster is pressed down and care taken that the tuberculin does not run from under the plaster. In from twenty-four to forty-eight hours a characteristic eruption resembling a tuberculide appears if the reaction is mild, and rose-red papules capped with vesicles or nodules appear if the reaction is intense. This test resembles the Moro test, and the author claims that it is just as sensitive as the von Pirquet. The percutaneous test of Moro is less sensitive than the von Pirquet and inferior to it. The test "par excellence" is the subcutaneous tuberculin test. Small (decimilligram) doses should be used. Three reactions should be noted: viz., the general, local, and focal. The general reaction consists of a rise in temperature, headache, malaise, chilliness, and even nausea and vomiting. The temperature should be taken every four hours for three days preceding the injection, and every two hours following the injection. A slight and temporary rise of temperature may not be observed if the thermometer is used only every four hours; and a dangerous focal reaction may result from a second larger dose. One must remember that in active tuberculosis tuberculin is a powerful poison and should be handled as cautiously as the poisonous alkaloids. A rise of at least 1° Fahrenheit is considered a positive reaction. Recent and active disease responds promptly to small doses. The local reaction is that usually seen at the site of a subcutaneous injection of any substance. The most valuable sign is the *focal reaction*. This consists of increased cough and expectoration, pain or feeling of oppression in the chest, breathlessness, an appearance of râles if previously absent, or an increase of râles if already present, and tubercle baccili previously absent may appear in the sputum. This reaction is specific for only a tuberculous focus can attract tuberculin and react to it in this way. Under contraindications to the use of tuberculin Riviere mentions the presence of fever, obvious phthisis, recent hemoptysis, recent severe illness, advanced arteriosclerosis, kidney disease, myocarditis, and epilepsy.

If in this paper I have succeeded in convincing you of the child's exalted place in the present era, and of the precedence that prophylaxis must take in our tuberculosis work, and of the diagnostic pitfalls that we may meet, then my effort has not been in vain, and I am sufficiently rewarded.

THE INFLUENCE OF AUTOLYTIC PRODUCTS ON TUMOR GROWTH.

By G. L. ROHDENBURG, M.D., and F. D. BULLOCK, M.D.,
NEW YORK.

FROM COLUMBIA UNIVERSITY, GEORGE CROCKER SPECIAL RESEARCH FUND, F. C. WOOD, DIRECTOR.

While the authors do not believe in the curative effects of autolytic cell products on tumors, so many supposed beneficial results have been reported by C. Lewin,[1] I. Levin,[2] Blumenthal,[3] Fichera,[4] and others, that further investigation of the subject, in order to determine whether any of the individual products have any curative effects, seems warranted.

Theoretically the results of treatment with autolysates may be due either to the intracellular enzymes concerned in the process of antolysis or to the chemical products of autolysis. We have restricted ourselves in our experiments to the chemical products, of which thirty-three different ones have been studied.

Crocker tumor No. 180, an invasive rapidly growing medullary carcinoma, was the neoplasm used. Fourteen days after subcutaneous tumor inoculation, mice in groups of ten were given daily injections of one-fourth c.c. of one per cent. solution or suspension of one of the various products (a dosage equal to nine gms. per diem for a 150 pound man). These injections were given subcutaneously in a region of the body remote from the tumor, and were continued for fourteen days. At the end of this period of observation the mice were killed and several tumors of each group were examined microscopically.

As will be noted in the table, with the exception of nucleinic acid from animal cells and phenylalanin, none of the various groups showed any variation from the normal course of growth. The typical course as observed in all of the other groups is well illustrated by the behavior of the group injected with glutaminic acid (see chart). Microscopically no changes were observed in the treated groups which were not also observed in the controls.

Effect on Tumor Growth

Chemical	Bigger	Stationary	Smaller	Disappeared	Number of Animals	Died
Controls	37	3	0	0	47	7

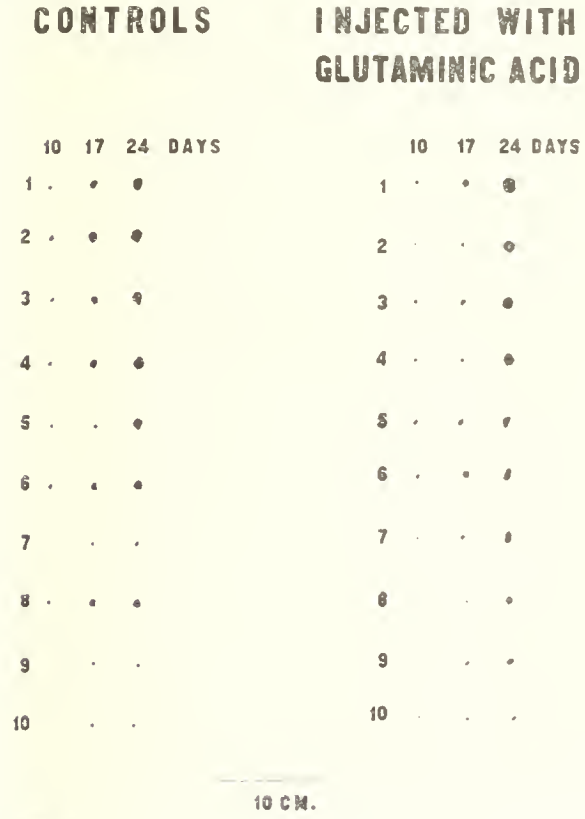
Skatol	7	0	0	0	10	3
Sodium Amido formate	9	1	0	0	10	0
Sodium Hippurate	8	1	0	0	10	1
Sodium Urate	8	1	0	0	10	1
Thymine	10	0	0	0	10	0
Tyrosin	10	0	0	0	10	0
Urea	10	0	0	0	10	0
Uric Acid	8	2	0	0	10	0
Xanthin	9	1	0	0	10	0

Inasmuch as one of the substances (nucleinic acid) which showed a very slight retarding influence (an influence, by the way, which is so small that it may be disregarded), has been recommended as a cancer cure, it was determined to repeat the experiment using the two products nucleinic acid and phenylalanin on a larger (40 to the group) number of animals. With the use of larger numbers the supposed retarding influence disappeared, showing again the fallacy of regarding slight variations in small numbers of animals as of any importance.

A final series of twenty-four animals was treated with protonuclein. Twelve of these animals were given daily injections of one-fourth c.c. of a quarter-of-one per cent. solution, the remaining twelve being given four times that dose, amounts equivalent to 2.25 and 9 gms. respectively, for a human adult weighing 150 pounds. After the third injection, seven of the twelve animals receiving the larger dose died suddenly in what appeared to be anaphylactic shock. The animals surviving the course of two weeks' treatment, nineteen in all, showed no difference in growth as compared with the control group.



Minor variations, or even differences of 10 to 20 per cent. in small groups of treated animals, are due to accidental and uncontrollable variations in the growth of neoplasm. This factor of error can be eliminated only by the employment of a much larger number of animals than are recorded in any of the published papers. A full knowledge of the biology of the tumor used is also necessary. Thus it has been shown (Wood and McLean[5]) that while one investigator has reported cures with a certain therapeusis using the Buffalo rat sarcoma, his deductions are faulty in that the tumor in question spontaneously recedes in from 5 to 40 per cent. of all inoculated animals. Variations in the rate of tumor growth occur also in parallel series of animals from the same source and under exactly similar conditions of inoculation site, dose of tumor, food, and

age of the animals. Unwarranted conclusions are too often announced because these facts are either not common knowledge, or, being known, are blithely disregarded.

Our experiments fail to show any inhibition of tumor growth when the chemical products of autolysis are used. In particular, nucleinic acid, derived from animals cells, and protonuclein are without effect on the malignant tumors of mice; their therapeutic use, therefore, in human cases can be expected to produce nothing but the psychic exaltation common to the use of every new remedy.

THE HIGH CALORY DIET IN TYPHOID FEVER.*

By KENNETH E. KELLOGG, M.D.,
NEW BRITAIN, CONN.
FELLOW OF N. Y. ACADEMY OF MEDICINE.

The progress of the science and art of internal medicine in the last few decades, and the application of modern knowledge to the management of infectious diseases, are in many instances equally radical, though perhaps less striking than the brilliant results achieved by contemporaneous surgery.

A good example is afforded by the high calory diet in typhoid fever, a drastic departure from the starvation method which not so long ago was considered as inseparable from the therapeutics of fevers in general, and enteric fever in particular. We have since learned that in disease no less than in health, the body requires an uninterrupted replenishment of its protein store.

Briefly sketched, the dietary history of typhoid fever is as follows: Eighty years ago, carbohydrate water, jelly, and broths were advocated by Graves. In the seventies of the last century, two quarts of milk made the daily menu for Austin Flint's patients. No dissenting voice was raised against an exclusive milk diet in typhoid fever until Shattuck, in 1897, advocated more liberal feeding, as he found no greater frequency of perforation or intestinal hemorrhage on a high than on a low calory diet in this disease. By a high calory diet is meant one of 4,000 to 6,000 calories daily, a considerable increase over and above the 1400 calories which were regarded as sufficient by Austin Flint.

The matter of feeding in typhoid fever was placed on a scientific basis in 1909, when the investigations of Shaffer and Coleman showed that the loss of protein, connected with the fever and inseparable from all the old restricted diets, can be lessened or altogether avoided, by means of a carefully selected diet of easily digested foods, notably carbohydrates, which protect the body-protein better than any other food. One of the chief objections against the high calory diet was removed when von Hoesslier showed that its use does not increase the temperature in typhoid fever.

At the time of its first introduction, the high calory diet aimed at supplying typhoid fever patients with the same food values as needed by a healthy person. Schottmüller, in Germany, now fixes the daily allowance at 130 to 150 g. of albumin, in typhoid fever; healthy persons require only about 60 g., as a little more than double that amount is needed to balance the disintegration-processes of typhoid fever. The body-albumin is indirectly protected against combustion by an abundant intake of carbohydrates, sugar, and flour. Approximately 40 calories per kilo of body-weight is a reasonable calculation.

The investigations of Du Bois have shown that contrary to expectations, the typhoid patient is perfectly capable of digesting and absorbing a high calory diet. At the present time the capacity of the gastrointestinal tract in fever to digest an abundant mixed diet is no longer doubted.

The absorption of fats is alone disturbed in the first stage of the disease, according to the findings of Du Bois. The normal course of digestion in typhoid fever is illustrated by the entirely normal appearance of the stools. There is less diarrhea with a mixed high calory diet than when fluids alone are given. Recent findings have shown that no more than 5 per cent. of the calories ingested is lost in the feces.

It is the aim and object of the high calory diet to protect the body against excessive loss in weight until the disease has either run its natural course or been cut short by measures of immunization. The importance of an abundant supply of carbohydrates is especially emphasized by all the advocates of the method, both in this country and abroad. Barrs, in England, and von Müller, in Munich, are leading foreign exponents of the high calory treatment, in form of a mixed diet, for typhoid patients. The plan is widely adopted in Russia.

The prevention and control of typhoid fever is one of the urgent problems of modern warfare. Writing from the seat of war, Dr. Romberg (of the First Medical Clinic, in Munich) emphasizes the decisive importance of a liberal diet, *i.e.* high calory feeding, from the very first day of the disease. He says that at least 30 to 50 calories per kilo of body-weight should be given every day. The failure of the general circulation in these cases is often merely the result of insufficient nutrition, not of the disease itself. Bedsores and furunculosis are likewise referable to under-feeding. The diet especially recommended by him consists of 2 to 2½ liters milk, ¼ liter cream, four to five eggs, porridges sweetened with lactose, on account of the liability of cane sugar to ferment. There is no objection against giving tender meats, scraped or minced, creamed toast, mashed potatoes, or purées of green vegetables. All these foods are transformed in the intestine into bland and innocuous chyme.

It is sometimes claimed that the high calory diet has substituted the classical milk menu of these patients, but this is not strictly true, in so far as milk forms the basis of the high calory feeding and can be exclusively given in the early stage of severe cases, up to an amount of 3,000 calories. In a case of well-marked anorexia, it may not be possible to persuade the patient to partake of other than liquid food, during the first week or two. Soups and porridges, prepared with 100 g. farina, rice,

*Read at the annual meeting of the Hartford County (Conn.) Medical Society, April 6, 1915.

oats, sage, or tapioca, are then in order. Other articles of food are gradually added, such as buttered toast, scrambled eggs, junket and custards, cereals, mashed potatoes, apple sauce, etc., until about 4,500 calories are reached, which is usually a sufficient quantity to offset the loss in weight due to the fever itself and the toxic disturbances in its train. In the steep curve period, and during convalescence, as pointed out by Coleman, patients take readily from 4,000 to 6,000 calories daily. Still higher feedings are sometimes advantageous. In his experience of over one hundred cases, the high calory diet apparently modified the course of the disease, shortened convalescence, and reduced the mortality. The incidence of hemorrhage and perforation was lessened.

The fear has thus been shown to be ungrounded that a solid diet, especially meat, might cause mechanical irritation of the ulcers, thereby favoring intestinal hemorrhage and perforation-peritonitis. The frequency of relapses is not in any way affected by the dietary régime of typhoid fever cases. A recurrence is now known to be a reinfection of the mesenteric lymphatic apparatus of the bowel, associated with a general infection of the blood.

In view of the fact that the infection originates from the lymph-vessels, but not from the intestinal epithelium, it is not likely that the passage of normal chyme through the ileum favors the onset of these recurrences. This is borne out by the findings of Kinnicutt, who analyzed 600 cases of typhoid fever, fed on a liberal diet, and noted that the number of relapses was not increased, while there was less hemorrhage and perforation than under the old method of treatment.

In describing the clinical picture of typhoid fever, as governed by the diet of the patient, Rajewski (1913) states that no bad results were observed to follow upon a solid diet. His observations were made upon 864 patients, who were kept on a diet of milk, meat, eggs, and white bread. Complications followed in 492 of these cases, primarily of the respiratory organs. Bedsores occurred less frequently than otherwise. The average duration of the disease was thirty days. The mortality amounted to 10.3 per cent., increasing with the patient's age and with the time which had elapsed between the onset of the disease and the day of admission to the hospital.

Recent very exhaustive studies of the influence on the high calory diet on the respiratory exchange in typhoid fever lead Coleman and Du Bois to the conclusion that the large amount of food administered exhibits no specific dynamic action, thus removing the chief theoretical objection to the use of a liberal diet in typhoid fever. Their observation of a sharp rise in the level of the respiratory quotients during the last days of the fever, in the majority of high calory patients, leads them to the interesting interpretation of this rise as marking the onset of regenerative processes, *i.e.* the beginning of convalescence, before the temperature has become normal.

Advantages of a Mixed Diet.—The patient is protected against inanition and progressive loss of strength, a fact which acquires special importance in the troublesome cases running a protracted course with repeated exacerbations and relapses. The organism which does not lose in weight becomes automatically more resistant, and develops an increased capacity for the formation of antibodies. Undoubtedly, a mixed and liberal diet tends to raise the general resistando, and thereby lessens the liability to secondary infections. Sicard, from an analysis of 29 cases occurring in the second division of Bellevue Hospital during the summers of 1911 and 1912 concludes that the most evident features of the high calory feeding are the maintenance of weight and nutrition, the appeasing of hunger, and the lessened tedium of convalescence.

A practical point worth remembering is that about three tablespoonfuls of granulated sugar, mixed with the liquid food, equal the addition of 50 g. to the diet.

There are certain disadvantages connected with a purely liquid diet which were not always taken into proper consideration when mapping out the dietary régime of a protracted disease, such as typhoid fever. The high calory diet does not tax the heart by an excessive amount of fluid, two liters being amply sufficient under a mixed diet, while nearly twice as much was formerly found necessary to maintain the patient's nutrition on an exclusively liquid diet. These large quantities of fluid were apt to favor the development of edema, in cases with a weakened heart-action. A minor although by no means negligible advantage of the full diet in typhoid fever is the resulting improved condition of the patient's mouth, tongue, and teeth, brought about by the act of chewing.

Following a safe medium course in prescribing the dietary of a given case of typhoid fever, it is advisable to adhere to the rule of Forchheimer, that every patient having the disease should be fed with reference to his digestive power, with exclusion of such articles as in themselves or in their residue may be irritating to the raw surface of the gut or may produce undue peristalsis. As to the amount of food to be given, so as to achieve the best results, conditions vary in individual cases, each patient being a law unto himself. The desire for nourishment, and the benefit obtained therefrom in form of added pounds to the patient's weight, are reliable guides in this respect. Not the disease, but the patient, must be the first care of the clinician, for individualization, based on scrupulous attention to detail, is the master-key to success in the dietetic treatment of typhoid fever as throughout the domain of internal medicine.

173 Main Street.

Esophageal Stenosis Following Typhoid Fever.—H. H. Grant reports two cases of this condition. One of the patients was a boy thirteen years of age who had had typhoid fever two months previously. At one time there had been considerable hemorrhage from the mouth. There had been frequent vomiting. Three weeks after recovery the patient first experienced difficulty in swallowing solid food. This gradually increased until no solids could be taken. Later practically nothing could be gotten into the stomach. The emaciation and exhaustion became so marked that gastrostomy was imperative as a life-saving measure. *X*-ray examination showed the site of constriction near the cricoid cartilage. At the preliminary operation the stomach was simply brought into the incision and anchored. The next day the stomach was opened and a tube inserted. Since then the patient has been nourished through this tube. The second case reported is that of a man who experienced difficulty in deglutition after recovery from a severe attack of typhoid fever. With the use of dilating bougies the lumen of the esophagus was practically restored in about three weeks.—*Pediatrics.*

New York, August 7, 1915.

A NEW THEORY OF THE CAUSE OF ENTEROSTASIS.

INTESTINAL stasis has been much before the medical profession and the public during recent years, owing largely to the very active propagation of his views by Sir Arbuthnot Lane and his followers. Both in Great Britain and in this country, however, a large number of medical practitioners have dissented from Lane's theory of the cause of intestinal stasis, some partly and others wholly, and the question has been made one for vehement discussion. A new view of intestinal stasis has been lately put forward by Dr. Arthur Keith, Conservator of the Museum of the Royal College of Surgeons, England, who took as his subject for the Cavendish lecture which he delivered this year a new theory of the causation of what he terms enterostasis (*West London Medical Journal*, July, 1915).

In this lecture Keith first pointed out the extent to which our knowledge of the living human body had been revolutionized by the discovery and application of the Roentgen rays. He found that an account published four years ago by L. R. Müller on the innervation of the bowel, states definitely that the myenteric plexus differs from a true nerve plexus both in structure and in staining reaction. He therefore adopted the working hypothesis that the myenteric plexus represents a nodal and conducting system. He says that, if he is right in presuming that the myenteric plexus represents in the intestine a system which corresponds to the nodal and conducting system of the heart, then it is also to be expected that both systems should be developed in a corresponding manner. The other parts of the alimentary canal where peristaltic movements are known to arise were examined carefully without results, and then the various sphincteric regions of the alimentary tract were examined and the conclusion was reached that there was such a nodal center at the gastroesophageal junction of the mammalian stomach.

When Keith's search for a nodal system along the alimentary canal had reached an encouraging stage he visited Dr. W. B. Cannon in his laboratory at Harvard University, who told him that Alvarez had lately discovered that the commencement of the second part of the duodenum dominated the rhythm for the whole duodenal loop. When the duodenal loop was cut out in segments and each segment kept alive in Locke's solution the rhythm or beat was fastest in the segment from the commencement of the second part and slowest in the segment from the end of the loop. On Keith's theory the upper segment had the greater amount of nodal tissue and was therefore the pacemaker of the duodenal rhythm. Alvarez found that the first segment of the jejunum had a slightly higher or faster rhythm than the last part of the duodenum, but that from the first part of the jejunum to almost the last part of the ileum the rate of rhythm decreased. At the last part of the ileum, if a piece of the ileocecal junction were left attached to it, the rate actually increased; but only if the ileocecal junction were left attached. This was explicable if Keith was right in regarding the ileocecal collar as a nodal center, as a pacemaker for the cecum and ascending colon.

Keith does not think either mechanical conditions or even derangements of sphincteric mechanisms can give an adequate explanation of all the phenomena of enterostasis. But when we transfer from the heart to the alimentary tract not only the anatomical and physiological data relating to its nodal and conducting system, but also our knowledge of cardiac pathology of heart block, or auricular fibrillation, of extra systole, and of delay in conduction, we seem to reach a more rational explanation of the motor derangements of the alimentary tract.

Keith does not agree with Lane in his explanation of enterostasis as the "drag, band, and kink" theory. In the first place Keith brings into the foreground the musculature of the alimentary tract, which is recognized at the sole propelling power in the intestinal wall. In Lane's theory a defect in the musculature of the bowel takes a very minor part in the causation of stasis. Further, Keith is of the opinion that his theory is the more in harmony with the appearances observed by clinicians and pathologists, and because it rests on a better basis of anatomical and physiological fact, he believes it will finally be accepted.

DYSPNEA AND ITS RELATION TO BLOOD REACTION.

IN 1913 Lewis, Ruffel, Wolf, Colton, and Barcroft described a peculiar symptom complex associated with reduced alkalinity of the blood occurring in elderly subjects. This symptom complex comprises continuous dypsnea, often intensified for short periods, especially at night; good or fair blood aeration as judged by the absence of cyanosis; Cheyne-Stokes breathing, with or without full apneic periods; an increase of pulse rate (80-100 per minute), and a subnormal temperature. This syndrome may be associated with uremic or cardiac manifestations, but the association is not a necessary one.

In a series of further observations upon this subject, Thomas Lewis and Joseph Barcroft (*Quarterly Journal of Medicine*, January, 1915), note that only in rare instances can the above symptom complex be recognized owing to the accompanying conditions—cardiac, renal, or respiratory—to which the dyspnea is usually attributed. In the later series of

cases the authors have studied the blood "acidosis," *i.e.* the excess of acid, exclusive of CO_2, in the blood as compared with the bases present, this acidity being determined by the percentage of saturation of the blood with oxygen when exposed at 37 deg. C. to 17 mm. pressure of that gas. The percentage of saturation of normal blood when exposed to the pressure is 75 to 80. In proportion as the quantity of acids relative to bases is excessive, the percentage saturation drops.

The fact that the dyspnea usually occurs in patients with cardiovascular or renal disease is apt to point to either of the latter as the cause. Nevertheless, the dyspnea may be out of all proportion to the degree of cardiovascular or renal impairment and the evidence of acidosis may be so pronounced as to leave little doubt that the latter is the actual cause. These facts are illustrated in the cases reported. In one of these a man fifty-three years old with signs of myocardial and renal disease suffered from nocturnal attacks of dyspnea; on two occasions there was distinct evidence of blood acidosis. Another man, aged forty-seven years, with cardiovascular disease, had dyspnea on exertion and nocturnal angina pectoris; acidosis was found. Four other cases are cited to illustrate the same association. Aortic disease was present in two of these cases, in one of which an aneurysm was also present.

Cases of heart disease are roughly divided into two classes. The first includes the relatively simple cases, in which, although cyanosis may be present, there is but little dyspnea. In these there is no acidosis. To the second class belong those cases of heart failure in middle-aged or elderly subjects in which acidosis is a frequent accompaniment, and in which the dyspnea is pronounced and persistent. The rôle of the kidney in the production of dyspnea in cases in which manifest disease of this organ is present is as yet veiled in obscurity. At any rate the reduced alkalinity of the blood as demonstrated in these cases leaves little doubt that this reduced alkalinity is an important factor in the production of the dyspnea. The suggestion is made that in the cases of acidosis one is dealing with a changed metabolism as profound in its symptomatic effects as is the altered metabolism of diabetes, and of greater consequence than the latter because so much commoner.

There are cases of dyspnea attributed to mechanical causes, in which cases, however, analysis of the blood shows that acidosis plays an important part in the causation. In this connection the important observation is made that in acute pneumonia there is present an acidosis during the febrile stage of the disease and for some time after the crisis, disappearing hand in hand with the breathlessness during convalescence. A case of exceptional interest is reported in which paroxysmal dyspnea, occurring in a man with signs of cardiac and renal involvement with aortic aneurysm, was associated with an exaggerated acidosis during the attack. In this instance the paroxysm of breathlessness may have been due chiefly if not entirely to a sudden flooding of the system with acid products.

THE AUTOMOBILE AND ITS DRIVER.

THE increasing use of the automobile, both for pleasure and for profit, has been accompanied by a far greater proportionate increase in the number of casualties incident to this mode of transit. Public authorities are beginning to awaken to the need of a more strict supervision of automobile traffic. The ordinances and regulations now in force are grossly inadequate in controlling incompetent and reckless driving. An absurd inconsistency exists in the law and practice in New York which requires an examination of the applicant for the chauffeur's license and at the same time exempts from examination the owner or private individual who drives his own car. An irresponsible youth or reckless schoolgirl may drive unmolested through the congested streets of a city or may speed unhampered along the country roads. The toll of severe injuries and deaths reported in the daily papers mark the lack of restraint upon this serious menace of public safety.

In checking this evil a number of measures are already operative. The fining and even the imprisonment of offenders are but poor deterrents. An educational campaign has been inaugurated by railroads, of course for their own interest primarily, in the use of "safety first" signs and warning bulletins. Societies of public safety have been organized. One of these in New York City has recently advocated the periodical inspection of all motor cars so that those with defective brakes, signals, lights, etc., may be barred from the streets and roads. This is an excellent measure for there can be no doubt that a fairly large percentage of all motor accidents are the results of defects in machinery, the consequence partly of cheap construction and partly of inefficient care by the owner. A far more important provision, however, would be the examination of the driver himself, not only as to his knowledge of the mechanism of the car, but also as to his ability to drive safely. All owners and drivers should be licensed, and, as has been the practice in Berlin for some time, no license should be issued until the applicant has demonstrated to the official accompanying him that he has the proper qualifications.

This leads to the subject that brings automobile driving within the sphere of interest of the medical man, himself an ardent devotee of the cult, namely, the psychology of the driver. As long as the automobile is a toy the owner will assume these personal risks that are inherent in all sports, with the exception, however, in this particular case, that the life and limb of individuals not partaking of this sport are seriously endangered. The pleasurable sensation associated with the smooth and rapid progression of the automobile tends to relax those psychic inhibitions that are an essential in all human pursuits. Hence the "mental brakes" are often at fault. If the driver is defective in his psychic makeup the recurrence of accidents befalling the same driver would apparently point to this deficiency—there is demonstrated a woeful weakness in the mental brakes. Another shortcoming is a lack of presence of mind. It is possible with

the simple tests of the psychological laboratory to determine the so-called "reaction-time" of the individual. His mode of reacting to various signals can thus be readily determined. If his response is slow or incorrect his obvious unfitness as a driver can be determined.

The fact that a large proportion of automobile accidents occur after "dining out" suggests the undoubted rôle of alcoholic stimulation in removing the restraining influence of prudence and caution. The exhilaration produced by an amount of alcohol that would not ordinarily intoxicate may be sufficient to transform a cautious driver into an unsafe and dangerous one. The effect of physical and mental fatigue in removing the barrier of wise mental restraint is almost too obvious to require comment.

To sum up, safe automobile driving requires sane laws and their efficient enforcement, a safe car, and a clear-headed driver.

THE PRACTICAL USE OF DISINFECTANTS.

After the discovery that many diseases are communicable, that is to say caused by the action of specific organisms of the most minute size, which have taken up their abode as parasites in the body of man or other members of the animal kingdom, disinfectants came into intelligent employment.

In *Public Health Reports*, July 9, 1915, H. E. Hasseltine, Passed Assistant Surgeon, U. S. Public Health Service, writes on the above subject. He points out that the ancients used heat and sulphur for purposes probably more or less allied to the disinfection of the present day, but the rational use of disinfectants did not begin until the early eighties, when bacteriology became a field for scientific work. Since that time they have been much used and much abused. Too much altogether has been claimed for disinfectants, and, as Hasseltine says, there are two terms often used synonymously, viz., disinfection and fumigation, but while they may be synonymous in certain cases, they are not necessarily so. To disinfect is to free from infectious or contagious matter, to make innocuous. To fumigate is to apply smoke, gas, or vapor.

Briefly summarized, the points emphasized by the writer are: (1) Disinfecting procedures, properly applied, have an important part in the prevention of communicable diseases. (2) Their efficiency decreases as the distance between the place of origin of the infection, the patient, and the point of their application is increased. (3) Natural disinfection, or the destruction of infection by processes of nature, increases in efficiency in direct proportion to the length of time and the degree to which the processes, drying, sunlight, etc., are allowed to act. (4) The point at which natural disinfection becomes sufficiently nearly complete to warrant the discontinuance of terminal disinfection should be determined under more exact conditions than have obtained in the past. (5) The choice of disinfectants must be made with due consideration of conditions, always bearing in mind that a good mechanical cleansing is one of the efficient means of disinfection. For gaseous disinfection formaldehyde, evolved by the formalin permanganate method under proper conditions of temperature and moisture, is the simple and most efficient method. (6) Control tests should be used to check the efficiency of disinfection. (7) Though the results obtained in some cities since abandoning terminal disinfection after certain diseases seem to show that heretofore much useless disinfection has been done, it is not felt that the evidence thus far adduced fully justifies its discontinuance.

A New Microorganism Causing Pulmonary Abscess.

This finding is reported by A. Josefson and L. Bladini in the *Beiträge zur Klinik der Infektionskrankheiten und zur Immunitätsforschung*, Vol. IV, No. 1. The microorganism was isolated from the pleural and pulmonary exudate in a man who had been admitted to the Royal Seraphim Hospital of Stockholm with the diagnosis of pleuropneumonia. Exploratory puncture of the left pleural cavity showed the presence of a thick, foul-smelling fluid of a sanguinolent color. At operation when rib-resection was performed the abscess cavity in the pleural space was found to communicate with an abscess in the lung, which was apparently the primary disease process and which had perforated into the pleural space. Patient recovered. Bacteriological examination of the germ isolated showed a gram-negative, capsule-bearing bacillus which was easily cultured. It was highly pathogenic for mice and, after four successive passages through these animals, also pathogenic for rabbits. In these instances the germ caused subcutaneous abscesses and after intratracheal injection, abscesses in the lungs. In one case a bacteriemia was demonstrated after an intratracheal injection was given. The new bacterium apparently belongs to the same group as the so-called Friedländer pneumobacillus. It differs from the latter microorganism in its appearance, and also in the fact that it is pathogenic for the rabbit. An important tinctorial reaction is perceived in the staining of the new bacillus blue by means of iodine, a property also shared by a leptothrix isolated from the lung by Leyden and Jaffé. In both instances, however, this peculiar staining property disappears in pure cultures.

Recent Views of Arteriosclerosis.

Among the revolutionary advances in our knowledge of arteriosclerosis must be reckoned the separation by Heller and his disciples of syphilitic endarteritis from arteriosclerosis. Not less important is the work of Jores in proving that so-called primary atheroma of the intima and arteriosclerosis are two phases of one process and not, as Virchow taught, separate affections. Aschoff, Benda, and others have shown in connection with child and animal (experimental) arteriosclerosis that fatty degeneration of the intima represents the début of the process. At a session last winter of the United Berlin Medical Societies (*Deutsche medizinische Wochenschrift*, May 13) Benda, in discussing a paper by Klemperer on arteriosclerosis, summed up the preceding statements. He added that very recently his pupil Fricke had succeeded in producing a typical "human" arteriosclerosis in a rabbit.

Various microscopic sections illustrated the crucial fact that fatty degeneration had occurred in tissues which had not been the seat of previous inflammatory proliferation. Such a find strengthens the belief in the toxic nature of the affection. Other factors might be required to explain the localization—which doubtless corresponds to the site of least resistance—such as functional strain and alimentary insults.

News of the Week.

Committee of American Physicians for the Aid of the Belgian Profession.—Dr. F. F. Simpson, treasurer, 7048 Jenkins Arcade Building, Pittsburgh, Pa., reports the receipt of the following contributions for the week ending July 31, 1915:

Washington County (Ark.) Medical Society, Fayetteville, Ark.		$ 14.00
Dr. J. F. Pressley, San Francisco, Cal.		5.00
Receipts for the week ending July 31st		$ 19.00
Previously reported receipts		7,750.84
Total Receipts		$7,769.84
Previously reported disbursements:		
1,625 Standard Boxes of Food @	$2.20..	$3,575.00
1,274 Standard Boxes of Food @	2.30..	2,930.20
353 Standard Boxes of Food @	2.28..	804.84
Total Disbursements		7,310.04
Balance		$ 459.80

Aid for Blinded Soldiers.—Miss Winifred Holt, who established "The Lighthouse," an institution for the aid of the blind in this city, sailed for Europe some time ago to organize a movement to aid the many soldiers blinded in the present war. She has opened a "Lighthouse" at Bordeaux, the first of several to be operated on the same lines as the one in New York. The official name of the Bordeaux institution is "Le Phare de Bordeaux pour les Matelots et Soldats Aveuglés sur le Champ d'Honneur." The enterprise has the enthusiastic support of the French military authorities and hospital officials. An American committee has been organized to attend to the financial end of the enterprise. It is known as the Committee for Men Blinded in Battle.

Winding Up the Typhus Campaign in Serbia.—The American Red Cross announces that Dr. Richard P. Strong, chief surgeon of the International Health Board at Nish, Serbia, had cabled that with $20,000 additional at his command he can finally free Serbia entirely of typhus and other epidemic diseases and put the country on a thoroughly sanitary basis. The money has been transmitted to Dr. Strong, $10,000 being donated by the Rockefeller Foundation and $10,000 by the Red Cross.

Recall of the Red Cross Units.—American Red Cross surgeons and nurses will be withdrawn from the European battlefield on October 1, because of lack of funds to maintain them longer at their stations. It is possible that the two units in Belgium, where the greatest need exists, will be continued, but the other fourteen detachments will return to the United States.

Award of the French Military Cross to an American Physician.—Dr. Richard Norton of Cambridge, Mass., founder of the American Volunteer Ambulance Corps, has been awarded the French military cross known as the "Croix de Guerre," for bravery in his work among the wounded on the battlefield. The Government, in sending him the decoration, stated that the cross was given "in token of his great bravery," especially for his heroic work in rescuing the wounded during the evacuation of a village within 500 metres of the lines of the enemy.

Death Rate in New York.—During the week ending July 24 there were 1,299 deaths reported in New York City with a rate of 11.67 per 1,000, as compared with 1,331 deaths and a rate of 12.44 during the corresponding week of 1914, a decrease in the absolute number of deaths of 32 and a decrease in the rate of .77 of a point, equivalent to a relative decrease of 86 deaths.

Death Rate in Chicago.—During the week ending July 24 there were 504 deaths in Chicago, giving a death rate 10.8 per 1,000, as compared with 12.5 during the preceding week and 14.8 during the corresponding week of 1914.

Child Labor in New York City.—According to law no child under the age of sixteen may be employed in any factory or mercantile establishment without having first secured a permit issued by the Department of Health. In order to obtain such papers the law requires that the child present a certificate of having reached at least Grade 7A in school. In addition to this, the child must pass a physical examination conducted by the Department of Health. During the quarter ending June 30, 1915, 10,606 permits were issued and 488 were refused. The total number of physical examinations made were 11,468.

Registration of Osteopaths Under the Harrison Law.—Federal regulations under the Harrison antidrug law have been changed recently to permit registry of osteopaths so they may administer drugs in states where they are registered by law as practitioners.

The Corinna Borden Keen Fellowship.—Dr. W. W. Keen has established a fellowship with this designation in the Jefferson Medical College, Philadelphia. The recipient of the fellowship, the income from which is $1,000, must study at least one year in Europe, America, or wherever he can obtain the best facilities for research in the line of work he shall select, after consultation with the Faculty, and must publish at least one paper embodying the results of his work as the "Corinna Borden Keen Research Fellow of The Jefferson Medical College." Application stating the line of investigation which the candidate desires to follow, to Dr. Ross V. Patterson, Jefferson Medical College, Philadelphia, Pa.

Pellagra.—At a recent meeting of the Louisiana State Board of Health Dr. Joseph Goldberger of the U. S. Public Health Service presented a report on pellagra, which stated that the disease is neither infectious nor contagious, but is purely and simply a dietary disease, due to a lack of animal proteins in the ration. It is not necessarily an unbalanced diet in the conventional sense, but a diet that lacks some essential constituent. Dr. W. P. Tucker of Nashville and Marcus Haase of Memphis agreed with Dr. Goldberger. They both stated that medical treatment had been eliminated in the hospitals under their control and excellent results were being achieved with a diet treatment. A rich full diet and cheerful surroundings were all that was needed, they held, to cure the disease. These views were also supported by Dr. Clarence Pierson, superintendent of the Jackson Insane Asylum.

New York and New England Association of Railway Surgeons.—The twenty-fifth annual session of this association, celebrating the quarter century anniversary of the organization of the association, will be held at Hotel Astor, New York City, Octo-

ber 21, 1915, under the presidency of Dr. W. H. Marcy of Buffalo, N. Y. A very interesting and attractive program has been arranged. Railway surgeons, attorneys, and officials and all members of the medical profession are cordially invited to attend. Further information may be obtained from the secretary, Dr. George Chaffee, 338 Forty-seventh street, Brooklyn, N. Y.

A State Board for Care of the Feebleminded.—Dr. Thomas W. Salmon, Medical Director of the National Committee for Mental Hygiene, recently presented to the State Constitutional Convention a petition for an amendment to the Constitution which would permit the Legislature to establish a special expert board to deal with the feeble-minded. The petition directs attention to the importance of providing institutional care or some form of guardianship in the community for the thousands of mentally defective persons who are now at large in the State. It says that a broad, constructive State policy for dealing with this subject can be formulated and carried out only by a special commission composed of those who have expert knowledge of the social, medical, and educational problems involved.

Nursing Care for Advanced Cases of Tuberculosis.—A formal agreement has been entered into by the New York City Department of Health with the Nurses' Settlement, whereby the latter will furnish nursing care for bed cases of tuberculosis in Manhattan and The Bronx recommended by the Department of Health. The cases are to be referred to the local office or local representative of the Nurses' Settlement by the branch offices, and thereafter no further visits are made by Department nurses, except in cases under the care of the Clinic Auxiliary, when the auxiliary continues on the case as a social worker. The regulations of the Nurses' Settlement forbid the nursing of patients not under a physician's care, so the Department of Health will furnish the necessary medical attendance for the patients cared for under the new plan, a clinic physician being assigned for that purpose.

Cheaper Radium Some Time.—Secretary of the Interior Lane announces that the production of radium from Colorado carnotite ores by the Bureau of Mines of the Department of the Interior, in connection with the National Radium Institute, has passed the experimental stage in its new process and is on a successful manufacturing basis. The cost of one gram of radium metal produced in the form of bromide during March, April, and May of the present year was $36,050. This includes the cost of ore, insurance, repairs, amortization allowance for plant and equipment, cost of bureau of mines salaries and all expenses. The secretary is at pains to add, however, that this low cost of production does not mean an early drop in the selling price of radium, which has been $120,000 to $160,000 per gram.

Dr. Charles F. Sanborn has been appointed superintendent of the new Greenpoint Hospital, Brooklyn, in the Department of Charities of New York City. He assumed his new duties on July 15.

Dr. Eva Harding of Topeka, Kan., announces that she will be a candidate for the Democratic nomination for Congress from the First Kansas District in 1916.

Dr. Harry D. McNeil of Bangor and John W. Sawyer of Dexter have been appointed by Governor Curtis of Maine medical examiners for Penobscot County to serve with Dr. E. T. Nealey, formerly the sole examiner for the county.

Obituary Notes.—Dr. DAVID STREETT of Baltimore, Md., dean of the Baltimore Medical College from 1888 until its amalgamation with the University of Maryland, School of Medicine, in 1913, and since that time professor of the practice of medicine in the latter institution, died at St. Agnes' Hospital, Baltimore, on July 30, aged 60 years. Dr. Streett was graduated from the College of Physicians and Surgeons, Baltimore, in 1878, and had served on the staffs of the Maternity, Mercy, and Maryland General Hospitals, and as a trustee of the last named and of the Baltimore Medical College. He was a member of the American Medical Association, the Medical and Chirurgical Faculty of Maryland, and the Baltimore City Medical Society.

Dr. GEORGE MORRIS DILLOW of New York, a graduate of the College of Physicians and Surgeons, New York, in 1875, emeritus professor of renal diseases at the New York Homeopathic Medical College and Hospital, consulting physician to the New York Ophthalmic Hospital, and a member of the American Institute of Homeopathy and the New York State Homeopathic Medical Society, died at his home on July 13, aged 68 years.

Dr. GEORGE J. DIRKES of Brooklyn, N. Y., a graduate of the College of Physicians and Surgeons, New York, in 1890, consulting physician to the Brooklyn Eastern District Hospital and Dispensary, and a member of the New York State and County Medical Societies, died at his home, from heart disease, on July 18, aged 48 years.

Dr. LAWRENCE BEN BITZ, JR., formerly of Pensacola, Fla., a graduate of the St. Louis University School of Medicine, St. Louis, in 1910, died at the home of his parents in Evansville, Ind., after a long illness, from tuberculosis, on July 10, aged 35 years.

Correspondence.

INTESTINAL STASIS AND EPILEPSY.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In the MEDICAL RECORD for May 22, 1915, in an editorial article entitled "Epilepsy from Many Angles," you state "C. A. L. Reed (*Southern California Practitioner*, March, 1915) advances the view that epilepsy is the result of a specific infection from the intestinal canal. The unknown organism is supposed to be a bacillus of gas-forming series . . . and favored in its growth by intestinal stasis resulting from mechanical conditions."

We cannot hold with Dr. Reed that epilepsy is the result of a specific infection from the intestinal canal, but we do believe that there are a large number of the so-called idiopathic epilepsies due to a chronic intestinal stasis—the condition so beautifully described by Sir W. Arbuthnot Lane. The idea of an "unknown organism" whose habitat is the intestinal canal is untenable we believe, but "stasis," that condition produced by a delay in the passage of the intestinal contents and its subsequent toxic action, we feel can produce and does produce conditions which when associated with an instability of the central nervous system, are responsible for the production of the epileptic manifestations. We do not feel that anyone who will take the time to visit an institution caring for epileptics can go away without being convinced that such a condition as chronic intestinal stasis exists, and on these premises we have for some time past been "short-circuiting" some of our cases with very favorable results, a report of which we will publish

in due time. It is understood, of course, that we are not including the traumatic cases or those with well-defined central involvement. How often is it the case where an epileptic is put on a careful regimen, kept under close supervision as to diet, etc., where every effort is made to promote excretion through all the emunctories, that we see an improvement in the patient's condition, and there is more reason why this improvement should be marked and permanent when we correct defects in the "drainage scheme."

G. KIRBY COLLIER, M.D.

CRAIG COLONY, SONYEA, N. Y.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

CROONIAN LECTURES—TRYPANOSOMES AND SLEEPING SICKNESS—RESEARCH DEFENCE REPORT—REPORT OF LOCAL GOVERNMENT BOARD.

LONDON, July 17, 1915.

THE Croonian lectures for this year have been delivered at the Royal College of Physicians by Sir David Bruce, F.R.S., C.B., etc. He took for his subject the trypanosomes causing disease in man and domestic animals in Central and Southern Africa. His own experience in Zululand, Uganda, and Nyassaland gave him the opportunity of studying those parasites *in loco*, so to say, and it may be assumed, until the contrary is shown, that what he tells us may be applied to every other pathological species that may be met with in that region, and very probably some exist there and are known under other names. The tropical, equatorial, or central region corresponds with the distribution of tsetse flies and these flies are the carriers of the trypanosomes which cause sleeping sickness. It was in 1877 that Dr. Timothy Lewis of the army medical department found in a rat a trypanosome which has been named after him the *T. lewisi*. In 1880 Dr. Evans, chief of the veterinary staff (Madras) found the *T. evansi*. There are other species of the parasite with different degrees of ill-effects on man and animals. The *T. gambiense* is essentially a parasite of man and the cause of the sleeping sickness as seen on the Congo; the *T. brucei* is the cause of the form met with in Rhodesia and Nyassaland, as well as of nagana in animals. These parasites pass through an invertebrate host—the tsetse fly—which, as it feeds on blood, preferably human, becomes the carrier of infection. At this point the lecturer interposed a description of the various forms of tsetse flies found in the same regions as the pathogenic trypanosomes, which developing in the intestine of the flies pass into the salivary glands, probably by way of the proboscis, completing thus their development into the infective forms. The fly does not waste time over its meals, but rapidly takes in, as opportunity admits, from $1\frac{1}{2}$ to $2\frac{1}{2}$ times its own weight of blood. It will often settle on the skin so gently as not to be perceived and will also insert its proboscis painlessly so that very little or no irritation may follow. But if there have been many bites close to each other there may result more or less swelling, induration, redness, and irritation for a few days. The groups with which we are chiefly concerned are (*a*) the *morsitans* and (*b*) the *palpalis*—the former lives in wild districts and principally depends on the game for food; the latter dwells rather by rivers or lakes and looks to man, to the human inhabitants, usually in such places, or, if none be found, reptiles; birds will serve. The antelope seems to afford a favorite supply.

In his second lecture, Sir David Bruce gave some very interesting notes as to his investigations on trypanosomes. When he went to South Africa in 1894 he was requested by the Government to report on a disease among native cattle, called nagana, and he trekked up to the north of Zululand, where it prevailed, and made bacteriological examinations of the blood and organs of infected cattle, with a negative result at first. But soon a motile body was found among the red corpuscles. Later this was seen to be a trypanosome, but was not supposed to be pathogenic until injecting the blood of nagana cattle into horses and dogs it was found to have a causal connection, but it was later still when nagana and tsetse-fly disease were shown to be identical. Then experiments were made to determine if the fly was the carrier of the disease, and it was proved that the *Glossina morsitans* and the *pallipedes* were so. Further investigations show that a large proportion of the wild animals living in the sleeping sickness district harbor pathogenic trypanosomes. In fly-free areas they have not hitherto been found. The *Trypanosoma gambiense* was first seen in 1901 by Dr. Forde, colonial medical officer at Barthmot, and as it was not known to him he referred it to Dr. Dutton of the Liverpool School of Tropical Medicine, who described and named it; but it was not until 1903 that the Royal Society's commission concluded that it was the cause of sleeping sickness.

Kleine was the first to prove that a tsetse fly could convey infection fifty days after feeding on a diseased animal. That was in 1908, and next year the lecturer confirmed this in Uganda.

For the first three or four days after a feed on infected blood the parasites are found in all. After a further similar period they have disappeared from most of the flies and only in a small percentage does further development occur. In about 95 per cent. the parasites die out in a few days, but in the remainder they multiply to countless swarms. How long infection of the fly continues is not absolutely known. One was found to retain its infectivity for ninety-six days. Trypanosomes taken into the tsetse flies retain their shape and infectivity for about eighteen hours and then degenerate and have usually disappeared by the fifth or sixth day. In the small percentage that remain they multiply in a different form. After twenty days or so they appear in the salivary glands in their original form. Cattle, though exhibiting no sign of illness, may be a reservoir of sleeping sickness. The antelope seems able to infect for at least eighty days, although the parasites are but few compared with the swarms in monkeys, and this may account for the continuance of infection after removal of native population, which it was hoped would not be the case.

The Research Defense Society held its annual general meeting on the 30th ult., when Lord Knutsford moved the adoption of the report and statement of accounts. The society has been in existence about seven years. Sir William Osler proposed the reelection of the officials, and paid a special compliment to the secretary.

The forty-third report of Local Government Board (1913-1914), Part I, has been issued, dealing chiefly with the Poor law, the unemployed workmen act, and the old age pensions act.

1. Alcoholism. E. B. Emerson.
2. The Cerebrospinal Fluid in Diagnosis and in Treatment. W. H. Watters.
3. Results of the Treatment of Pyorrhea Alveolaris and Allied Conditions with Emetine Hydrochloride at the Danvers State Hospital—Preliminary Report. H. I. Gosline.

1. Alcoholism.—E. B. Emerson states that environment and heredity underlie most cases of drunkenness. A craving for alcohol is not inherited, but the weak and unstable nervous system which renders the individual liable to excess in all things renders him especially susceptible to alcoholic indulgence. The mental disturbances produced by the latter present every possible variation, from simple intoxication to profound dementia. The psychoses especially dangerous are those characterized by active hallucinations and delusions. Acute alcoholic hallucinosis arising on a basis of chronic alcoholism is characterized by a sudden onset, with auditory, visual, tactile and olfactory illusions or hallucinations, accompanied by persecutory delusions and little clouding of consciousness. Recovery, with little or no intellectual damage, usually follows a first attack. In acute alcoholic hallucinosis auditory hallucinations predominate, whereas in delirium tremens visual hallucinations predominate. There are two common types of chronic delusional states differing in mode of onset and clinical characteristics. In one there is usually a history of previous attacks of delirium tremens, or acute hallucinosis, in which there has been an apparent recovery, or the disease may represent the termination of an acute alcoholic hallucinosis. The other type, sometimes called alcoholic paranoia, is characterized by the gradual development of a paranoid condition in middle life in subjects who have been steady drinkers, without previous acute mental disturbance. The disease is marked by delusions of suspicion, persecution, and jealousy, usually centering about the wife or husband.

2. The Cerebrospinal Fluid.—W. H. Watters concludes that lumbar puncture is a relatively simple and safe procedure when properly performed. Examination of the fluid removed should include chemical, microscopical and serological tests. By examination of the fluid it is possible usually to recognize with certainty and to differentiate the various forms of infectious meningitis. Repeated lumbar puncture is not infrequently of definite therapeutic value in such cases. The cerebrospinal fluid should be carefully studied prior to discharging as cured any case of syphilis, irrespective of the stage in which it has been treated. Examination of the fluid is an essential in properly following the treatment of cases of syphilitic involvement of the nervous system.

3. Emetine in Pyrorrhea Alveolaris.—H. I. Gosline employed emetine in the treatment of forty-two cases grouped as spongy gums, very spongy gums, and spongy gums with loose teeth. The treatment was the so-called full treatment and the local treatment. The full treatment consisted in the administration of emetine hydrochloride, 1/6 grain, twice a day subcutaneously, and the application of the wine of ipecac to the gums twice a day for one week, followed by a second week's treatment in which the gums were swabbed with wine of ipecac and an injection of emetine hydrochloride, 1/3 grain, was administered once a day. Of fourteen cases with spongy gums, eleven showed marked improvement, two moderate improvement, and one slight improvement. Of the twelve cases of very spongy gums, those treated locally showed only moderate or slight improvement, while those treated with emetine in addition to the local treatment showed 87.5 per cent. marked improvement. The group with loose teeth and spongy gums showed 78.6 per cent. marked improvement, but in no case with loose teeth did the teeth become firmly set once more.

4. Diastolic Blood Pressure.—J. S. Ferguson notes that there have hitherto been in vogue two ascultatory methods of reading the diastolic pressure: (1) By reading the approximate point of transition from sharp to muffled sounds; (2) by reading the last sound heard, viz., the end of the fourth phase. To these the author would add a third method, viz.: (3) Reading the level of the first sound heard on slowly returning from the fifth phase to the higher level of audible taps. For this third method there is claimed the advantage of a sharper point of demarcation than is possible with the first method, and the consequent elimination of a considerable portion of the errors due to the personal equation and the entire elimination of uncertainty as to the exact point at which the sound is to be read. The new method is said to have the advantage over the second method in that it much more closely approximates the true diastolic pressure; its readings are usually two to five millimeters above those by the second method, i.e. the difference is just about that which usually obtains between the first and second methods. In the absence of aortic disease, its results nearly always fall within the limits of successive readings by the first method. By its use the characteristic diastolic blood pressures of aortic disease cannot be overlooked. Moreover, it is not subject to variations dependent upon the rapidity with which the observation is performed.

8. Functional and Organic Heart Disease in Children.—M. H. Bass reviews the means of differentiating between the two. A large percentage of cases of functional cardiac disturbance occur in the so-called asthenics who are usually in their second decade, often about the age of puberty. They have grown rapidly and are therefore rather thin and narrow chested. The scapulae project, the abdomen protrudes, there is distinct lordosis of the lumbar spine, and the child stands in a relaxed, round shouldered posture. The epigastric angle is narrow, the tenth rib is free and not attached to the other costal cartilages. These children flush easily and often show dermographia to a marked degree. Chvostek's sign, obtained by tapping on the cheek over the facial nerve, is frequently positive. The vasomotor system is unstable, as is shown by the very red lips, the pale face, and the cold, blue, clammy hands, though blood pressure examinations fail to show any particular departure from the normal. The morning urine is free from albumin, but after the child has been on its feet for a time, albumin appears often in astonishingly large amounts. This peculiar type of juvenile neuropathy, called by Mackenzie *x*-disease, and corresponding to Stiller's asthenia congenitalis, is a very common clinical picture, and any cardiac signs or symptoms found in such a case are much more likely to be due to functional than to organic disease. By

means of the orthodiagraph one may determine whether or not the heart is of normal size, and gain also valuable information as to the shape of the heart. The elongated or "drop heart" is apparently part of the asthenic habitus. A slight ventricular hypertrophy such as occurs in the nephritis of children may be detected with the aid of the orthodiagraph. Certain forms of congenital heart disease prevent typical heart shadows. As regards murmurs it is pointed out that the majority of functional murmurs are cardiopulmonary in origin, and for this reason may be found to vary in intensity, depending on the phase of respiration, being usually loudest at the end of inspiration and faintest at the end of expiration. Change of the child's posture may change the character, and pressure of the stethoscope may change the loudness of such murmurs. Variability is characteristic of functional murmurs. Irregularity of the pulse is very common in children, chiefly in those of the asthenic habitus. The prevailing type of irregularity is the sinus arrhythmia, in which a number of slow beats are followed by a number of more rapid ones. This type of irregularity often disappears on exercise.

1. Treatment of Burns.—A. Ravogli recommends for a burn of the first degree the application of dry powders, such as talcum powder, bismuth, or alum. If there is severe pain and in second degree burns compresses moistened with a solution of aluminum subacetate, 2 to 5 per cent., should be applied. When the blisters are distended with serum the fluid should be drained off by puncture. Oily substances, such as carron oil, etc., must be avoided as possibly aiding infection. When shreds of epidermis are easily detached, they are cut off with scissors and a thumb forceps. The Sneve treatment, exposing the surface to plain air for an hour at first, and later two or three hours, is very useful. The treatment for a third degree burn is nearly the same. Recovery is obtained through cicatrization. The plain air and sunlight stimulates the granulating surface. It must not be forgotten that the granulations need to be touched with a solution of silver nitrate every other day to prevent irregular or keloidal scar. After exposure for from two to three hours the wound must be covered with a suitable dressing, such as a 2 per cent. borated petrolatum on English lint. When the granulations are pale and show a tendency to pus formation, the application of a mixture of castor oil and Peruvian balsam also gives good results, but cannot be continued for a long time on account of the irritation produced. In burned areas of large size without a tendency to epidermis formation, a few Reverdin epidermic grafts are of value. Any extensive burn of whatever degree has a systemic reaction. In the beginning the patient may suffer from shock. More often there may occur gastroduodenal ulceration with continuous vomiting and sometimes nephritis and pneumonia. The fever following a burn rises and falls somewhat like that of typhoid. The administration of quinine is very useful. In nephritis the intravenous injection of Fisher's solution with the internal administration of digitalis is helpful. Gradually as the patient improves, and when the fever is gone, a substantial diet with an iron tonic preparation must be given.

4. Influence of Age and Sex on Hemoglobin.—C. S. Williamson finds that the hemoglobin value is greatest at birth. The decline begins at once and continues until at the fifth month the average value is nearly down to the minimum (about ten-seventeenths of the value at birth), and far below the average adult figure. From then on until the end of the first year it diminishes slowly and reaches the minimum in the second year of life. There is then a fairly rapid rise up to the sixteenth year and the variations are relatively small and the curve is nearly horizontal from then on to the sixty-fifth year. After seventy-six in men there is a slight rise, but the decline continues in women. The values are then identical in both sexes up to the sixteenth year. From then on to the seventieth year the sex differences manifest themselves, and the values for women are in every instance lower than those for men. Beyond seventy-one the values for both sexes come together and are practically identical.

7. Infection of Urinary Tract in Children.—By C. G. Grulee and F. W. Gaarde. (See MEDICAL RECORD, July 3, 1915, page 38.)

14. Treatment of Gonococcal Vulvovaginitis.—C. C. Norris states that desiccation quickly destroys the gonococcus. The organism does not thrive on squamous epithelium, except that of the immature variety, such as is found in the vagina of the young. Despite the fact that virulent organisms are constantly being deposited on the vulva and in the vagina, gonococcal inflammation of these areas is unusual in the adult. With these facts in mind, it is evident that cleanliness and drying should be important factors in the treatment. In most cases it is worth while to sacrifice the hymen, thus affording better drainage with more thorough treatment and cleanliness. Silver solutions are the principal therapeutic agents, beginning with a 1 or 2 per cent. solution of silver nitrate gradually increased, to be used three times a week, and during the interim the vagina should be washed out daily with a weak potassium permanganate solution as a cleansing measure. The success of the treatment is dependent largely upon its thoroughness and regularity, and one may consider a cure has been effected when negative findings are obtained after three consecutive bacteriological and physical examinations made at fortnightly intervals after all treatment has been discontinued, the last examination being preceded by chemical irritation of the vaginal walls with silver nitrate to reveal any remaining gonococci.

6. Sigmoid Tortuosity of the Internal Carotid Artery and Its Relation to Tonsil and Pharynx. A. G. Fisher.

1. Trypanosomes.—Sir David Bruce in this, the fourth of the Croonian Lectures, concludes his exposition of the present knowledge concerning these microorganisms, which may now be referred to three groups and nine species. In regard to the transference of the virus from sick to healthy animals by the fly this has been made clearer and easier of comprehension by the discovery of the part which the salivary glands and hypopharynx play in the various modes of development which the trypanosomes undergo in the fly. It results that it would almost appear impossible for an infective fly to pierce even momentarily the skin of a healthy susceptible animal without causing infection. Another important feature is the proof brought forward that *Trypanosomo brucei* and *Trypanosoma rhodesiense* are the same. Finally, in regard to the prevention of these trypanosome diseases of man and domestic animals, it has been shown that the wild game in the fly country is heavily infected. It is impossible to doubt that they are the reservoir and source of many of these diseases. There can be little doubt that if the wild game were driven out of the fly country trypanosome diseases such as those caused by *Trypanosoma brucei* and *Trypanosoma pecorum* would disappear. In regard to the measures of prevention against the most important of all the trypanosome diseases—Congo sleeping sickness—it has been shown by experience that the removal of the natives from the fly area is a simple and efficacious way of stopping an epidemic. In these sparsely inhabited countries, where spare land and food are easily obtained, there is, as a rule, no difficulty in effecting this migration. If it is desired to go a step further and render the sleeping-sickness area inhabitable, then clearing and cultivation must be resorted to. By these means, in all probability, *Glossina palpalis* will be driven away, and with it the disease.

2. Breast Feeding.—H. K. Waller emphasizes the need for correlation between (1) the periodicity in the secretion of milk, (2) the size of the meals, and (3) the infant's appetite. The breast tissue fulfils the physiological law that to obtain the maximum output of work a suitable stimulus must be applied at a suitable interval. The total quantity of milk secreted in 24 hours is greater when the number of meals given is 6 rather than 9 or 10, and greater still when the 6 give place to 5 and 4. This change to the smaller numbers can be made about the sixth or eighth week. A child can take 7 ounces of food from the breasts at one meal as early as the twenty-first day. If appetite be considered as an expression of digestion, the author's observations show that large infrequent meals do not disagree with quite young infants. The cry of the overfed—*i.e.* of the too frequently fed—is commonly mistaken for the cry of hunger.

3. The Binet-Simon Method in Adult Prisoners.—M. Hamblin Smith concludes that the Binet-Simon method is an excellent means of estimating the standard of intelligence of any particular subject. The method, having been primarily devised for use with children of school age, would be rendered more useful for adults if certain modifications were made in its details. Defect of intelligence, as estimated by this method, affords strong confirmation of a diagnosis of feeble-mindedness made upon other considerations. Failure to reach any given standard of intelligence is not of itself sufficient reason for regarding a subject as feeble-minded.

4. Capacities of Mental Defectives for Future Work.—W. A. Potts states that a defective who at school is either very good at manual training or merely good at manual and also at every school subject, is certain to get work afterwards, unless he has some serious disability in addition to mental defect. First-class readers have the best prospects, but reading does not draw the line as manual work does. Arithmetic gives a better clue. Writing is also some guide—at any rate, in a negative way; it is so much easier to teach a defective to write than to read or calculate that he must be of a low grade if he does not learn at all. Finally, as regards individual tests, among the simpler ones Warner's hand-balance is useful at any rate from a negative point of view, weeding out some who will never hold their own in the world. It is a simple test, easily applied, but too unscientific for the up-to-date psychologist who will prefer something like the ataxigraph, an elaborate instrument with small bodes of various sizes in a brass plate; the subject has to hold a needle in one of the holes without touching the plate for 15 seconds. An electric battery is attached, and touching the plate makes a contact and causes a click, all contacts being recorded. Smaller holes are tried till the subject has reached the limit of his capacity and is clearly unable to keep the needle from contact with the plate. The dynamometer may afford an index of general bodily strength. Several investigators have found a correlation between strength of hand and mental ability. Other tests are provided by the form-board, the estimation of the quickness of movement by noting the rate of tapping, the measurement of reaction-time, etc. The greatest importance, however, is to be attached to the opinion of an experienced physician as to the capacity of a mental defective.

5. Complete Rupture of Uterus.—J. F. R. Seheult notes that while there is still some diversity of opinion with regard to the best method of treating cases of rupture of the uterus generally, it is now universally conceded that abdominal section, although tending to increase the shock which usually already exists, is the correct surgical procedure when the rupture is complete and extensive. The question of extirpating the uterus or merely repairing the rents in the organ depends largely on attendant circumstances. Once the abdomen is opened hysterectomy does not seem to involve a greater degree of shock than does the suturing of lacerations in the uterine wall, and the time occupied by the former operation should not exceed very much that involved by the latter procedure.

6. Sigmoid Tortuosity of Internal Carotid Artery.—A. G. T. Fisher points out that when the sigmoid tortuosity lies in the coronal plane it is liable to injury in operations involving the posterior wall of the pharynx. Before such an operation as the removal of adenoid vegetations from the nasopharynx abnormal pulsation should be felt for, as fatal hemorrhage has occurred from injury to the internal carotid artery during this operation. That the abnormal pulsation is due to a sigmoid tortuosity of the internal carotid artery and not to the ascending pharyngeal artery seems to be now definitely proved. When the sigmoid tortuosity lies in the sagittal plane, it is more likely to be met with in operations on the tonsil. Although it is usually stated that cases of fatal hemorrhage after removal of the tonsil or incising a peritonsillar abscess are not due to injury of the internal carotid artery it seems not unlikely that some of the cases are due to this cause. In the latter case no measure short of ligature of the common carotid artery is likely to be of any avail, though even this measure may fail owing to the free anastomosis between the carotids in the circle of Willis. Again, in injuries or bullet wounds involving the throat which have led to severe primary or sec-

ondary hemorrhage one must remember not to be obsessed by the rigid text-book description of the internal carotid artery.

6. Trypanosomes Causing Disease in Man and Domestic Animals in Central Africa. Sir David Bruce.

5. Elastic Tissue.—W. Ewart notes that the history of the elastic fiber is a standing problem which the inferior elasticity of indiarubber does not help one to solve. The elastic fiber is destroyed in the lung by overstrain in emphysema and by disuse in obesity, and it is then disposed of readily by phagocytosis. The mystery is its surprising normal "endurance." This would almost seem to be a function of its mechanical exercise, even more than of its nutrition. Facts have been recorded which demonstrate a patchy local "regeneration." But of its "alimentation" nothing is known except that the fiber can be stained. And yet, if we assume that it grows, like the length and breadth of the muscular and tendinous fibers, it should be, at any rate at that stage, receptive of nourishment. On the other hand, when full grown, its vital exchanges are of a minimal order; and its viability and function are largely dependent upon motile and hygrometric factors, while apparently independent of direct innervation. The late J. W. Roosvelet of New York devised a method of preserving the lung post-mortem in such manner that for a long time this organ may be made to expand and contract in an apparently normal manner. The vesicular murmur can be plainly heard in it, and percussion gives the same note as obtained from fresh lungs. The process is a modification of the old glycerin-carbolic method, well known and often used to preserve anatomical specimens in an elastic condition. If, as appears, the elastic fiber has in its mechanical keeping one's individual polyorganic architecture, might it not conceivably be itself the builder; and, if so, might it not then be the missing link between one's physics and vital energy?

6. Trypanosomes.—By Sir David Bruce. (See page 244.)

Berliner klinische Wochenschrift.

July 14, 1915.

Case of Acute Farcy.—Wolff relates the following case which illustrates the great difficulty in the diagnosis of this affection. The patient was a hostler who first developed headache, high temperature and stiff neck without a positive Kernig. There was marked sensitiveness over the left shoulder joint. There were cases of glanders among the horses, but the symptoms did not point in that direction. The pulse was notably slow despite the temperature of 40° C., which showed only slight morning remission. Diarrhea and a leucopenia (3,700) were present. The diazo reaction was negative. The picture suggested in part typhoid, in part epidemic meningitis. Standing out, however, was the peculiar joint lesion, which suggested a pseudo-rheumatism. This proved to be periarticular and was the only symptom which actually suggested farcy. The hypersensitiveness was extreme, mere contact with the biceps tendon at the joint capsule causing the patient to cry out. One week after the earlier symptoms the patient's general condition was wretched. He presented, however, little or nothing abnormal in the mouth, throat, and nasal passages and but little cervical adenopathy. There were no cutaneous or visceral manifestations, save a doubtful enlargement of the spleen. The fever curve was not characteristic of any affection and rather suggested sepsis than the other continued fevers. Nearly a week passed without change in the picture, which now suggested a typhoid bacteriemia or sepsis. The mental state showed some implication. A day or two later, however, the elbow joint showed the same implication as the shoulder, and soon afterward a nodule appeared in the upper arm between the two affected articulations. With this the clinical picture rapidly changed to that of farcy. Infiltrations appeared in the lower extremity. A discharge of mucopus began from the nostrils. Serodiagnostic tests were positive for farcy. The patient went rapidly from bad to worse and nothing exerted any possible influence over the process. Extensive infiltrations appeared in the face and forehead, backs of hands and feet, and showed a tendency to become universal. The sheaths of tendons, subcutaneous tissues and skin were all involved, the latter exhibiting pustules and blebs. The former were at times very small, resembling an outbreak of acne. The general state was that of severest sepsis. Neosalvarsan was tested without benefit. With such a degree of sepsis the patient could not possibly have recovered. The author neglects to mention whether the *Bacillus mallei* was found, but this could hardly have been absent. According to Tochmann acute farcy may be confounded with typhoid fever, sepsis, polyarthritis, and erysipelas. An erysipelatous blush accompanied some of the infiltrations in the cases reported by Wolff. The resemblance to meningitis is not mentioned.

Diagnosis of Farcy in Man.—Gildemeister and Jahn mention the great infrequency of human farcy. In Prussia from 1907 to 1912 but sixteen cases were reported, and of this number ten proved fatal. Infection from man to man as well as from horse to man may occur. The authors have had the unusual fortune to see three cases which they give in brief. A lad of eighteen was attacked with an inflamed wrist which he attributed an an accident. Fever appeared at the same time. Within a short interval all the joints in the four extremities were involved. At the end of two weeks this condition began to wear away, but painful nodules appeared over some of the joints and on the forehead. These attained the dimensions of a walnut or plum and then underwent softening. They were incised and evacuated. Although no further activity was shown the patient was not improving, for the abscess cavities refused to heal and temperature was present off and on. The patient probably has chronic farcy with prognosis in doubt. The two other patients presented similar cases, in that periarticular troubles represented a preliminary stage and were followed by foci of suppuration. In both, however, acute glanders developed, i.e. the nasal discharge which characterizes one type of the disease. In patient No. 2 the face was studded with so-called farcy boils, and in patient No. 3 bullæ appeared over the farcy abscesses and discharged a bloody pus. Both patients succumbed to the disease, one of heart failure from toxemia, while the other showed the full picture of sepsis. The bacillus mallei was obtained in culture from the first two cases, and in all three, the authors stated, positive agglutination, complement fixation, and conglutination tests were obtained.

Münchener medizinische Wochenschrift.

June 15, 1915.

Medical Blunders in the Practice of Military Surgery and Their Avoidance.—Goebel in his capacity as adviser of hospitals—field, military and reserve—has seen many infractions of the precepts of military surgery. This is inevitable, for physicians in civil practice have been suddenly called upon to practise something in which they have had no special training. The surgeon thinks in terms of wound dressings and operating rooms and of attendants who aid in preparations for operation, in narcosis, etc. In cases in which the former civil practitioner has tried to fit up an operating room the author has noted many errors. The possibilities were not utilized, light was defective, everything was unhandy. Naturally the asepsis was faulty, the attendants incompetent. A sister with the operation already under way was sterilizing various articles and disinfecting her hands on the operator's time; finally, she drew on a pair of sterile rubber gloves! Some physicians greatly overdid the gloves, and when their hands were thus protected took hold of soiled dressings or opened doors, etc., without a thought of asepsis. Soap and sublimate were used jointly for disinfection! It was ludicrous to see careful and excessive sterilization of dishes, etc., followed by some blunder which undid all the good. Rubber gloves were often ruined because it was not known how much talcum was required to shake into them before sterilization. Wet dressings and the circular bandage were used when contraindicated. Tampons were employed when light gauze dressings would have been proper. Dressings were so applied that healthy joints were immobilized, a capital error. Where need of fixation was imperative, the fastening was sometimes only "symbolical." Plaster dressings were not fenestrated. With some extension splints there was no counter extension, and weights were too light. There seems to have been a general lack of understanding as to how to apply fixed dressings for ultimate functional results. If the rule was known—as semiflexion in extension—the exceptions were unknown. Passive motion after joint immobilization was neglected. The rule for narcosis in certain cases when extensive dressings have to be changed was ignored, as in fractures of the spine and thigh. Finally, and perhaps in the long run worse than any other error, says Goebel, is the neglect to make autopsies.

More German Substitutes for Foreign Proprietaries.—Winckel gives the German equivalent for much advertised French, English, and American proprietaries of the type used by very many practitioners in all countries. A syrup of hypophosphites is prepared as a sweetened solution of several of these salts. A sedative very widely known is reproduced under the name of "solution of bromated chloral." A certain pioneer emulsion of cod liver oil is reproduced as "compound emulsion" of the same. These represent the best known of a large number. At the same time Germany is going ahead with new proprietaries, most of which have only a restricted sphere of action. One is a synthetic, the 2-phenylcinchonate of strontium, which is recommended for gout. A nutrient substance which is purin free may be mentioned in the same connection. An aromatized acetylsalicylic acid tablet is said to possess slight radioactive properties and is presumably intended for use in true rheumatism. A celebrated firm places on the market a partially caramelized sugar—literally a mixture of several polymerized products of sugar. It can be used as sugar in mild and medium diabetes to the extent of 100 gm. daily. The remainder present little of novelty or interest.

Deutsche medizinische Wochenschrift.

June 10, 1915

Symptomatology, Diagnosis, and Treatment of Typhoid Fever.—Schultze states that hardly anything actually new can be said of typhoid and that one can only call attention to certain aspects of it, for example, a febrile typhoid. A small number of well authenticated cases of the latter are upon record. These represent a mild type of infection. Diagnosis is made by the usual methods. Cases of almost afebrile typhoid are also recorded, in which the temperature rise is slight and only occasionally present. Strange to relate, such cases may begin with a pronounced chill. The initial chill is the exception in typical typhoid and does not occur at all in the elderly. Severe chills are sometimes seen in the course of typhoid, even during the stage of decrease of fever. But relapses are seldom ushered in with chill. Intercurrent chills seldom stand in relation to complications. They sometimes precede a fatal termination, and may be part of a collapse picture. The headache of typhoid may or may not be associated with increased tension of the cerebrospinal fluid. Another causal factor may be the action of the typhoid toxin on the meningeal nerves. Herpes labialis is of small percentage incidence in typhoid. In regard to Brand's method as tested on a series of medium and severe cases in the author's clinic the usual mortality was improved but 1 per cent., although by manipulation of figures this improvement could be computed as 4 per cent. (10 per cent. as against 14 per cent.). The author in a particular epidemic lost but 6.6 per cent., a figure which Brand's method cannot improve on. Like most clinicians the author makes free use of cold water therapy, but in a less severe form and with some selection of cases. He likes small doses of pyramidon because they relieve headache, the latter interfering markedly with the patient's nutrition by depressing the appetite. In regard to diet the author has never pushed solid food because in recent years his patients have done well without it. High calory feeding does not seem adapted to patients with enteritis, diarrhea, and meteorism. In convalescence even the first solid food may send up the temperature. The author adheres to milk and eggs, prepared albumins, cereal decoctions, and gelatine jellies with zwieback, toast, finely minced meat, and vegetables. He mentions two cases of failure of immunization to protect soldiers, and advocates it under urgent circumstances only, as when soldiers are hurriedly mobilized. He regards the method, however, as entirely safe, for while local and general reactions may occur in exceptional cases, they are always transitory and insignificant.

Bullet Wounds of the Stomach and Intestines.—In one of the field hospitals 72 cases of bullet wounds of the abdominal cavity have been treated. The results in stomach injuries have been more favorable than those in intestinal wounds. Of these 72 cases 10 had no proper records. The total mortality was 45 or 63 per cent. Of fifty patients shot through the intestines, forty-two died or 84 per cent. Of thirteen patients shot through the stomach but two died, a mortality of but 15.3 per cent. This remarkable showing aside from the fact that in both fatalities large blood-vessels were severed—seems to have been due to the empty state of the organ at the time of the injury. Again the higher the wound the better the prognosis. The treatment of these stomach wounds should be conservative and intervention is indicated only in hemorrhage. The high mortality of intestinal wounds demands the creation of special field hospitals, the writer of the report states, because these cases cannot be transported for at least two weeks.

Insurance Medicine.

The Surgical Kidney with Reference to Life Expectation.—Dr. J. Allen Patton, Associate Medical Director, Prudential Insurance Company of America, Newark, N. J., states that this subject has been called to his attention a number of times during the past two years by the necessity of deciding upon a number of applicants who had had one kidney removed, besides many other cases where surgical treatment had directly involved the kidneys. With reference to the test used to determine the capacity of the kindneys, he quotes Crockett's claim that the phenolsulphonephthalein test gives the best results, as the dye is excreted from the kidneys in the same percentage whether the urine is free or scanty, and the rate is unaffected by diuretics, blood-pressure, or anemia, and it will foretell uremic conditions even in the absence of clinical, chemical, or microscopical signs. A decreased phthalein output indicates increased urea in the blood unless the patient is edematous or is being flushed with diuretics. Bariglit's scheme shows that albumin and casts lose their pre-eminence as diagnostic signs, for they both may be present in every type of renal disorder, hence are of no value in differential diagnosis. The phthalein test is of more value in prognosis than in diagnosis, for it determines the severity more than the type of the renal lesion.

Renal decapsulation is indicated in all varieties of chronic nephritis in the absence of conditions absolutely contraindicating any surgical procedure, and the earlier in the course of the disease the operation is performed, the better will be the chances of a perfect cure. Decapsulation only starts the cure of chronic nephritis and from months to two or three years are necessary to produce full results. The general consensus of opinion is that surgical procedure for movable kidney should only be employed after all medical treatment has failed, or where there are severe attacks, frequent Dietl's crisis, due to kinking or torsion of the renal vessels or ureters, hydronephrosis, or extreme mobility preventing the patient from following his usual duties.

W. W. Keen has stated that overweights are more subject to kidney diseases, having a lessened resistance, and renal colic combined with overweight has a bad showing. According to P. A. Muller, stone in the kidney demands operation and free secretion of urine to prevent stone recurrence.

Anuria may be divided into: (1) Obstructive; (2) reflex or paralytic; (3) non-obstructive or nephritic. Obstructive anuria demands a nephrotomy not later than forty-eight hours after the onset of the symptoms. Reflex anuria may also require a nephrotomy, and here one must decide upon which side to operate.

Pilcher agrees with Rovsing, Israel, etc., that there is no record of a cured case of renal tuberculosis having been demonstrated at autopsy, and Harpester states that one-half of all essential hematuria cases are due to tuberculosis of the kidneys, and that blood associated with dysuria or pyuria is very indicative of tuberculosis. It is generally accepted that the tubercle bacilli reach the kidney by way of the blood stream and that primarily the infection is unilateral. The course of the disease is progressive and only operative measures can effect a cure.

Kümmel summarized the after history of 386 of his nephrectomy cases and showed permanent cure in 80 per cent. of the tuberculous, 40 per cent. of the malignant tumors, 90 per cent. of pyonephrosis, and 98 per cent. hydronephrosis cases. He gave an excellent prognosis in unilateral injuries, but poor in cases of nephritis. He placed the limit for permanent recovery at two years in tuberculosis and four years in malignant tumors, this being the limit upon which he based permission for the women to marry, for then they would pass through pregnancy, as a rule, without disturbance of the renal functions. He reported seventeen cases of such pregnancy with only one premature birth and one nephritis. Nephrectomy does not seem to affect the course of subsequent pregnancies. Pinard believes marriage is permissible for girls, even after nephrectomy for tuberculous kidney, if the urine is free from bacteria. Homans stated in 1901 that a person with a diseased kidney removed might live to be very old, as the sound kidney could be fully equal to the work required; but, if a person recovers after a kidney removal and is well and strong, he has had enough good fortune and ought to be content without life insurance.

Patton considers that most of the medical directors of the present day seem to agree with the sentiments expressed by Dr. Homans twelve years ago. Fifty-two out of sixty-four medical directors were interviewed as to the practice of their departments with reference to applicants giving a history of nephropexy, nephrotomy, and nephrectomy. The answers were varied and rather vague. Four failed to answer; five had had no experience; eight declined; four would treat each case separately, one stating that they must trust to luck. Simple cases, where the statement showed recovery, were accepted after varied lengths of time; some in six months; others in six years. The inference is drawn from the replies that complicated cases would not be given consideration by any of the companies. Nephrotomy cases would be declined by sixteen companies and nephrectomy cases by thirty-four companies without any consideration, and all were united upon the rejection of cases of tuberculous or malignant disease in which there had been either a nephrotomy or a nephrectomy. The cases would be considered on their merits or individually by eight in nephrotomy, and four in nephrectomy. Five companies declined nephrotomy cases outright because of abscess. One took cured cases after one year; two after two years, but one of these on substandard forms only; one after three years, depending upon the case; three after five years.

Requests were sent to 100 surgeons with reference to nephrotomy and nephrectomy cases. Replies were received from thirty-eight, but of these only eight contained any information of value, while most of the others stated that they had not been able to keep in touch with their operated cases, or their data had not been kept up in a manner that would enable them readily to answer the questions. The above results would indicate that the average surgeon would probably be able to tell a prospective patient his chances of surviving the operation itself, but that very few surgeons could give a definite statement, based upon their own work, concerning the ultimate success of their kidney operations with reference to the comfort and duration of life of their patients.—*The Urologic and Cutaneous Review.*

Book Reviews.

A Text-book of Diseases of the Nose and Throat. By D. Braden Kyle, A.M., M.D., Professor of Laryngology and Rhinology, Jefferson Medical College; Consulting Laryngologist, Rhinologist, and Otologist, St. Agnes' Hospital; Fellow of the American Laryngological Association, etc. With 272 illustrations, 27 of them in colors. Fifth Edition, Thoroughly Revised and Enlarged. Price, $4.50 net. Philadelphia and London: W. B. Saunders Company, 1914.

Five editions of this work have appeared during a period of fourteen years and during this time it has maintained a high standard among the textbooks of its class. The present edition represents a thorough revision, with the addition of the following new articles: Vaccine therapy, lactic bacteriotherapy in atrophic rhinitis; salvarsan in the treatment of syphilis of the upper respiratory tract; sphenopalatine ganglia neuralgia; negative air presence in accessory sinus disease; chronic hypoplastic ethmoiditis; congenital insufficiency of the palate; lactic bacteriotherapy in pharyngeal affections; and an article describing the removal of a plate of artificial teeth from the esophagus. A large number of alterations and additions have been made to various chapters. As in the previous editions, the various diseases are discussed in relation to systemic conditions; etiology and pathology are dealt with quite fully, and diagnosis and treatment are given in satisfying detail. The volume is profusely and handsomely illustrated.

Seuchenentstehung und Seuchenbekämpfung. Kurzer Leitfaden für praktische Ärzte und Studierende. Von Prof. Dr. F. Neufeld, Abteilungs Vorsteher am Institut für Infektionskrankheiten "Rob. Koch," Berlin. Mit 24 Abbildungen. Price, 4 M., 50 pf. Berlin und Wien: Urban & Schwarzenberg, 1914.

This small flexible manual of 204 pages is designed to present the main facts regarding the spread of the most important infectious diseases, and the measures to be taken in combatting them. There is an introductory chapter on the general aspects of the prevention of epidemics, and then follow chapters on typhoid fever, paratyphoid fever, and meat poisoning, botalism, dysentery, cholera, bubonic plague, diphtheria, tuberculosis, smallpox, epidemic meningitis, poliomyelitis, Malta fever, malaria, relapsing fever, and typhus. One of the important features of this volume are the statistical tables and graphic curves which show at a glance the essential facts regarding the incidence and mortality from the above diseases.

A Practical Textbook of Infection, Immunity, and Specific Therapy, with Special Reference to Immunologic Technique. By John A. Kolmer, M.D., Ph.D., Instructor of Experimental Pathology, University of Pennsylvania; Pathologist to the Philadelphia Hospital for Contagious Diseases, etc. With an Introduction by Allen J. Smith, M.D., Sc.D., LL.D., Professor of Pathology, University of Pennsylvania. Price, $6.00 net. Philadelphia and London: W. B. Saunders Company, 1915.

The subject of immunity has become such a tremendous thing that we have here a work of nine hundred pages which is really a manual of immunological technique, accompanied by sufficient discussion and explanation of the theory to make the technique intelligible. The book is very complete. All of the immunity reactions are described clearly and in detail, together with their possibilities of error and their value and application. There is ample consideration of the general principles of immunity without a confusing consideration of controversal points. The book also contains an outline for a laboratory course in experimental infection and immunity. It is a valuable work and one that no immunologist can afford to be without.

A Laboratory Manual and Textbook of Embryology. By Charles William Prentiss, A.M., Ph.D., Professor of Microscopic Anatomy in the Northwestern University Medical School, Chicago. With 368 illustrations, many of them in colors. Price, $3.75. Philadelphia and London: W. B. Saunders Company, 1915.

This book is especially adapted for the use of the medical student. It combines brief descriptions of the vertebrate embryos which are studied in the laboratory with an account of human embryology. The methods and the results of the dissection of pig embryos form an important part of this work. Following an introduction, there are chapters on The Germ Cells; Segmentation and Formation of the Germ Layers; The Study of Chicken Embryos; The Fetal Membranes and Early Human Embryos; The Study of Pig Embryos; Methods of Dissecting Pig Embryos; Development of the Face, Palate, Tongue, Teeth, and Salivary Glands; Entodermal Canal and Its Derivatives; Urogenital System; Vascular System; Histogenesis; Morphogenesis of the Central Nervous System, and The Peripheral Nervous System. One of the excellent features of this work consists in its illustrations which, indispensable in every book on embryology, are in this instance particularly ample and clear. There are also a number of colored plates. One can have no hesitation in recommending this book to the student and practitioner.

A Textbook of Medical Chemistry and Toxicology. By James W. Holland, A.M., M.D., Sc.D., Emeritus Professor of Medical Chemistry and Toxicology, and Dean, Jefferson Medical College, Philadelphia. Fully illustrated. Fourth edition, thoroughly revised. Price, $3.00. Philadelphia and London: W. B. Saunders Company, 1915.

The fourth edition of this well known work on medical chemistry has been greatly increased in value by the inclusion of many of the newer chemical tests. Some of these are important, but others, such as, for instance, Saloman-Saxl's test and Abderhalden's test for pregnancy, have hardly been sufficiently verified to warrant their being taught to the student as in any way useful. No important errors have been detected, but certain expressions should be changed in the next edition. The statement (page 29) that "The kinetic theory is based upon the observation that 1 c.c. of a gas has 21 trillions of molecules" is dangerous for the beginning medical student. He might think that these molecules had really been seen. Under carbon monoxide (page 101) it should be stated that the spectroscopic method is so insensitive that it is rare that the presence of carbon monoxide hemoglobin can be demonstrated by this procedure, and other of the more sensitive chemical tests should be given in this paragraph. Still another paragraph which might be improved is that (page 250) stating that "If a sealed tube containing radium be immersed for a day in normal salt solution and then removed, the solution contains the emanation." Despite a few such errors, however, the volume is of great value and contains a large amount of very practical information for the student of medicine.

Medical Electricity, Röntgen Rays, and Radium. With a Practical Chapter on Phototherapy. By Sinclair Tousey, A.M., M.D. Consulting Surgeon to St. Bartholomew's Clinic, New York City. Second edition, thoroughly revised and greatly enlarged. Containing 798 practical illustrations, 16 in colors. Price, $7.50 net. Philadelphia and London: W. B. Saunders Company, 1915.

This is a work of considerable size. There are 1219 pages, of which 52 comprise the index; the size of the latter gives one an idea of the extensive scope of the subject matter covered by this volume. About one-half of the text is devoted to the subject of electricity which is dealt with under the following headings: Static Electricity; Dynamic Electricity; Electricity Occurring in Plants and Animals; Physiological Effects of Electricity; Electropathology; Electrodes, Electrodiagnosis, Ionic Medication by Electrolysis; Examples of Galvanic, Faradic, and Sinusoidal Electrotherapy; Physiological and Therapeutic Effects of Electromagnets; High-frequency Currents, and Phenomena Accompanying the Transmission of Electricity through Gases. There then follows a chapter on phototherapy. The greater part of the second half of this work is devoted to the *x*-rays, including a detailed description of the technique of the use of this agent, and of fluoroscopy and radiography of special parts of the body. A wide sphere of usefulness of the *x*-rays is discussed in connection with the treatment of various diseases such as trachoma, goiter, pernicious anemia, carcinoma, sarcoma, etc. Radium and its therapeutic uses are discussed in the concluding 40 pages of this volume. The present edition shows evidence of considerable revisions and enlargement, chiefly with the addition of new matter on Diathermy, Sinusoidal Currents, Radiography with Intensifying Screens, Röntgenotherapy, Radium Therapy, etc. There are also included several of Machado's tabular classifications of electric methods, effects, and uses. The volume is profusely illustrated. It presents a complete and authoritative exposition of the subjects enumerated above.

Society Reports.

SEVENTH PAN-AMERICAN MEDICAL CONGRESS.

Held in San Francisco, Cal., June 17, 18, 19, 20, and 21, 1915.

THE PRESIDENT, DR. C. A. L. REED, OF CINCINNATI, OHIO, IN THE CHAIR.

Addresses of Welcome.—Dr. C. A. L. REED of Cincinnati opened the Seventh Pan-American Congress by a brief address, in which he expressed his pleasure in presiding over the Congress because he had participated in the original Pan-American Congress twenty-two years ago and had watched with pride its growth and the part played by its members in the solution of the health problems of the American Republics. Its influence now extended from the North Sea to Cape Horn and the literature emanating from it found many eager readers throughout the Western Hemisphere.

SURGEON GENERAL RUPERT BLUE of the United States Public Health Service welcomed the guests of the Congress in behalf of the United States Government, taking as his theme the significance of such a meeting of representative medical men from so many American republics at the present time when international relations all over the world were so complicated. It gave proof of their devotion to the high ideals to which they were committed and showed that we of the Western Hemisphere were in accord.

Mr. CHESTER H. ROWELL, representing Governor Johnson, welcomed the guests in behalf of the State of California. He spoke of the part played by the Pan-American Medical Congress in welding together the temperate and tropical zones of the Americas and congratulated the medical profession as being the only body of men in the world who recognized no frontiers save the frontiers of knowledge, who recognized no social, no political, no partisan lines and no lines in war. His was the only service of love left in war. In closing he stated that he and the people of California were especially interested in the medical profession because it was through its members that they hoped to keep the plague in the Orient.

Dr. HENRY O. MARCY of Boston made an address of welcome in behalf of the American Medical Association in which he spoke of the part played by that organization in advancing the frontiers of medicine.

Addresses were also made by the official representatives of the South American republics, among them being Dr. Enrique B. Demaria for Argentine, Consul General P. de Obarrio for Costa Rica and Panama, Dr. Enrique Barnet for Cuba, Consul General Juan Chavez for Ecuador, Dr. Juan Padella for Guatemala, Dr. Luis De Bayle for Nicaragua, Dr. Carlos Morales for Peru, Dr. Carlos Leiva for Central America, Dr. Francesco A. Resquez for Venezuela, Dr. Alvaro Ramos for Brazil, Dr. Lorca P. Arturo, Consul for Chili.

Military Surgery.—Dr. HENRY O. MARCY of Boston read this paper before the Section on Surgery. He reviewed the history of the surgery of the battlefields of the prehistoric races of which he had made a study in the collection of Professor Putman in the Peabody Archæological Museum at Harvard, which showed the nature of injuries sustained by the Mound Builders, and also of a collection of bones found along the mountains of Peru. Among the latter were 4,800 crania which must have belonged to a period twelve to sixteen hundred years ago. He showed that Homer was not unmindful of the skill and ability of the surgeon in the Trojan war, that Egyptian surgery foreshadowed our modern antiseptic treatment of wounds, that the military surgeon in the Roman army held a position of respect and honor. He showed that the Napoleonic campaigns had added to our knowledge of military surgery, and of these advances not the least was the putting in practice of sanitary precautions, among which was vaccination against smallpox. The regeneration of France was largely due to the medical history of the Napoleonic campaigns and the men who served in them. After the Napoleonic wars France became the center of medical science. Then later the German universities took the central place in the development of the medical sciences and this rivalry of attainments was one of the sources of national jealousy and a potent factor in the present European war. Much had also been learned from the Crimean War. Dr. Marcy gave a very graphic description of his call to service in the United States in 1860, at which time he was associated with Surgeon General George A. Otis, author of "Surgery of the Rebellion." He stated that during the Civil War there were 6,000 surgeons and assistant surgeons appointed. The deaths in the Federal Army numbered 304,369, less than one-third of which were the result of the casualties of battle. In the Confederate Army there were 200,000 deaths, three-fourths of which were due to disease. The record of the injury due to alcohol in the Civil War was beyond estimate. The deleterious influence of alcohol was being recognized in the present war and efforts were being made to restrict its consumption. It had been shown that alcohol slowed the power to see a signal, confused prompt judgment, spoiled accurate shooting, hastened fatigue, and lessened resistance to disease. A comparison of the gunshot wounds of fifty years ago with those of the present day showed the former to be much more lacerated and almost necessarily infected, while those of the present caused surprisingly little damage to most of the structures. It seemed evident that wars quickened the desire for surgical and medical knowledge and hence medical departments of the army should be given more power and in certain matters supreme power. By no possible means could war be humanized. It was therefore the part of surgical science to mitigate its untold story of suffering as far as possible. In peace the medical department of the army was devoted to the advancement of science and the uplift of mankind. Our present knowledge, if mandatory, would divide the suffering, double the production, and increase by a third the longevity of the race.

Problems Associated with Compound Comminuted Fractures.—Dr. ROBERT T. LEGGE of Berkeley, Cal., presented this paper in which he stated that formerly most fractures of this kind resulted in amputation. As the result of modern industrial conditions compound comminuted fractures were more frequent than formerly. This fact was recognized and first aid packets were provided by many big corporations. Efficient first aid minimized the serious results in injuries. However the treatment of many injuries of this nature taxed to the utmost the ingenuity of the surgeon in devising appropriate methods. The essayist described the proper cleansing of these wounds with gauze swabs dipped in antiseptic solution, such as carbolized water. He emphasized that care must be exercised not to remove pieces of bone indiscriminately, since small pieces might be cleansed and replaced so long as they were attached to the periosteum. Large fragments also should be left even if detached, or even in suppurative cases these pieces sometimes united. Bleeding vessels were to be secured by fine catgut and tags of tissue that were badly damaged should be cut away. Collections of blood should be removed and blebs, swelling and tension should be relieved by stabbing and the application of antiseptic dressings. It was his practice to enlarge open wounds for further inspection and for the relief of interposed soft parts. In no instance should plates, screws, or metals be used in open fractures since all of these open wounds must be treated as though they were infected. He suturd the tissues with silkworm gut, watched circulation, employed gauze drains and changed the compresses daily. The difficulties of reduction were referred to and the importance of taking an *x*-ray before applying a plaster cast was emphasized. A three-board splint properly padded was recommended for leg injuries requiring the recumbent posture and the proper means of securing extension were considered. Fractures of the humerus might be splinted with one short encircling wire mesh. Fractures in joints when the result of gunshot wounds should be treated as comminuted fractures and the reduction of these was imperative or ankylosis would result. The necessity for amputation was determined by the degree of injury to soft parts. When it was evident that amputation must be done it should be done at once or as soon as the condition of the patient permitted. If gas bacillus infection developed amputation must be done immediately.

Some Phases of the Pathology of Appendicitis; Their Clinical Significance and Treatment.—Dr. HUGO O. PANTZER of Indianapolis read this paper in which he stated that he had made it a practice to look for anatomical evidence of chronic appendicitis both in the appendix and in the associated organs. From his ex-

perience it might be said that an acute appendicitis which at operation did not show gross evidence of chronic periappendiceal involvement having clinical significance was relatively rare. Even in cases in which appendectomy was performed as a prophylactic measure it was surprising how often evidence was found of inflammatory changes in the appendix, mesoappendix, or cecum and proximal ileum. This observation was not generally heeded. Peritoneal adhesions, bands, and membranes due to infection, the toxins of stasis, or congenital bands played an important part in the causation of stasis and resulted in pathological changes in their structure. Just as the pharyngeal lymphoid structures stood as the portal of the digestive tract, so a rich lymphoid structure of the iliocecum maintained an identical function in its location; at operation there was found a thickened and indurated wall of cecum and proximal ileum and a complement of enlarged and clustered glands. This condition was not much known or described and to this omission was due a large number of the failures to afford relief by removal of the appendix. The essayist emphasized the importance of searching for these periappendiceal and pericecal membranes, bands, and adhesions. Relief usually followed division of such bands and membranes, and they were also shown to regress after division. Such division furthermore made the appendix easily accessible. Appendectomy should be followed and supplemented by medical treatment both before and after operation. If chronic intestinal autointoxication was present it should be treated as should also insufficiency kidney, skin, or liver functions.

Extensive Resection en Bloc for Carcinoma of Breast with Lantern Demonstrations.—Dr. CARL BECK of Chicago presented this communication. He stated that this operation made it possible to eradicate a cancer of the breast reaching even into the region of the neck. The technique was comparatively simple if one was accustomed to extensive resections. He prepared a large flap for a cover for the wound from the upper part of the arm and shoulder. The arm with the shoulder girdle was removed just as in an ordinary shoulder resection, the flap left being somewhat larger. He removed the manubrium portion of the clavicle, either by exarticulation or section and pulled the clavicle from the body, exposing the whole region of the neck. He left only what he wished to leave behind and what he considered healthy. He sometimes found the nerves, blood vessels, and the subclavian artery wrapped in the cancer. Care must be taken in cutting the nerves. He had performed this operation nine times in eight years with the result that four patients were still alive, one five years after the operation. Every one of these cases had been declared absolutely inoperable.

Surgery of the Heart.—Dr. D. C. STRONG reported a case of stab wound of the heart and emphasized the fact that aseptic measures which were sufficient for successful peritoneal surgery were not sufficient for heart surgery. In heart surgery asepsis must be even more strict than in bone surgery. One should be satisfied with nothing less than Sir Arbuthnot Lane's technique. In order to prepare the surgical field properly four or five minutes longer than was customary might be taken with safety. Nothing but the gloved finger and the needle carrying the suture should be permitted to enter the wound. Sponging and traumatism should be avoided. One should plan his procedure before beginning to work. It must be emphasized that the method of conducting the average operating room was incapable of caring for these cases. In a case in which there was reason to suspect a heart wound exploratory incision was warranted. The edges of the wound should be approximated as perfectly as possible and the suture applied simultaneously with the heart beat. A very small opening in the pericardium should be left for the escape of fluid.

The Relation of Bovine Infection in the Child to Clinical Tuberculosis in the Adult.—Dr. F. M. POTTINGER of Monrovia, Cal., read this paper, in which he stated that it had been fairly determined that bovine tuberculosis could be transmitted to human beings; that it was accountable for about 10 per cent of tuberculosis, but that human infection was accountable for most of the disease in the human race, and that bovine infection was common in children but was rarely found in adults. The essayist quoted German and English statistics showing the relative infrequency of bovine infection. It seemed from these figures that bovine infection was particularly common in those types of tuberculosis found in children in which it might be supposed that infection had taken place through ingestion. It seemed that they must either believe that bovine infection for the most part became non-virulent or healed, confining its activity to the child, or that the bovine bacillus changed its type by residing in the body of man. It produced quite a large percentage of the clinical tuberculosis of childhood and as far as could be judged seemed to be well able to adapt itself to the soil and to thrive. That it thrived equally well with the human did not seem probable. The probability that seemed most worthy of acceptance was that these different bacilli, after living in the human tissues for a time, adapted themselves to the new conditions and gradually became the bacilli which would naturally be produced on human soil. This view was opposed by certain experiments, but there might be a sufficient difference between a rapid repeated passage through animals and a prolonged sojourn in the human body. Bearing on this theory was the fact that bovine bacilli were taken into the body through the same mucous membrane of the gastrointestinal tract as the human bacilli were. They took the same course thereafter, causing local infection in the lymph glands or in nonlymphatic tissue with secondary involvement of the lymph glands. Thus far there seemed to be no difference, although the assumption was probably correct that bovine bacilli did not infect the human organism as readily as did the human bacilli. At this point all changed. The bovine baccillus either produced metastases at once or went on to active tuberculosis or were never heard of again as bovine bacilli. The human bacilli might either produce metastases now or at any future time and were still human tubercle bacilli. If bovine infections became inactive to break down later in life, the same as the human infection did, it certainly did not show as a bovine infection when it again became active. The most rational explanation of the facts observed required the acceptance of the idea of transmutation.

A Plea for More Accurate Study of the Functional Efficiency of the Stomach.—Dr. ROBERT POLLOCK discussed more particularly what he termed the "slowly elaborating stomach," by which he meant the stomach having the greatest secretory efficiency at a time later than one hour following test meals. Many of these stomachs proved quite efficient when one understood them aright and treated them accordingly. Cases were cited which showed that this was not a rare condition, that it was not the accompaniment of any one pathological condition, and that it might occur in many normal persons. This condition admitted of many variations. Each individual type could be clearly outlined by the application of the fractional method of study. A close scrutiny of the data thus obtained would suggest lines of treatment for the relief of the patient's symptoms. While the outlay of time spent in the working out of these problems was considerable the time was well spent.

Precancerous Dermatoses.—Dr. HAZEN of Washington, D. C., presented this paper, in which he advanced two contentions: (1) That practically all the malignant growths of the skin developed from preexisting abnormalities, and (2) that the medical man in the course of his physical examinations should recognize these abnormalities and warn his patients of the dangers associated with them. Pigmented moles, non-hairy moles, congenital naevi, seborrheic keratoses, senile warts, cutaneous horns, and subepidermal nodules were apt to end in malignancy. The ulcers of syphilis and tuberculosis were also apt to become malignant. Wens, eczema, psoriasis, and acne rarely ended in malignancy. Extensive scar tissue and unhealed tissues sometimes developed malignancy.

The Cause of Carcinoma.—Dr. A. E. ROCKEY of Portland, Ore., read this paper. He stated that his thesis proposed that cancer was caused by a defensive process of the tissue cells to a great variety of irritations and that there was no specific external cause for cancer. In cancer there was a displacement of active cells of epithelial origin into the mesoblastic tissues. The cells were not a mature epithelial type, but were embryonal in character and irregular in development. By reason of their displacement they could not attain the normal anatomical perfection and physiological activity of mature cells. Their entire energy was therefore expended in karyokinesis. This karyokinetic energy developed in the cell was a defensive reaction to an irrita-

tion which to produce cancer must also destroy the basement membrane and produce a similar defensive reaction in the connective tissues. The writer then compared well known types of cancer, external and internal, and showed that there was no specific external cause for cancer, and that the defensive process above described was the only one common to all varieties of cancer.

The Tropical Diseases of Venezuela.—Dr. Z. A. Risguez of Venezuela read this paper, in which he stated that malaria was the principal endemic disease of his country. It had been impossible up to the present time to employ prophylactic measures for its prevention. In hemoglobinuria the great question was which was the morbid agent that by combining with malaria produced the hemoglobinuric attack. It was stated that this condition occurred only in subjects that had previously suffered from kidney disease. In Venezuela malaria was not treated by quinine, but with acids, chloride of calcium, and a mineral serum. Leprosy and tetanus prevaled to an alarming extent. Tetanus was found mainly among infants, who died in incredible numbers from it. They had made great efforts to prevent the spread of leprosy by forbidding marriage among the infected and by isolating patients, but it spread to an appalling degree. They now had five leprosy hospitals.

The Serum Diagnosis of Tuberculosis in Relation to Immunization and Prophylaxis.—Dr. Enrico Castelli, delegate from the Faculty of Medicine of the University of Genoa, Italy, presented this communication, to which an entire session of the Section on General Medicine was devoted. He described a method of serum diagnosis of tuberculosis which he and his colleagues of the University of Genoa had recently perfected after twenty-five years' work. By this method it was possible to determine by actual measurement the amount of tuberculosis infection, the degree of immunity against the disease, how much tuberculosis serum must be introduced into the body to obtain complete immunity and how long the immunity would last. By this method it was possible to immunize milk, eggs, and meat. The steps by which the writer proposed to immunize the human being of the future were: (1) By vaccination of the mother during pregnancy. (2) Vaccination of the child between the ages of one and six months. (3) Vaccination of milk-giving cows in order that babies might drink immunized milk. It had been proved that immunization was still active four and one-half years after inoculation, but to make immunity continuous revaccination would have to be performed at certain intervals. The immunity might last longer than four and one-half years, but of that they were as yet uncertain. Dr. Castelli said that before the outbreak of the war an extensive campaign had been mapped out for Italy in accordance with the following program: (1) An extensive and regular use of the serum diagnosis in hospitals, dispensaries, and private practice to secure earlier recognition of tuberculosis. (2) Compulsory vaccination of all babies under six months of age. The vaccination had been proved absolutely harmless. (3) Recommendation of the vaccination of pregnant women. (4) The establishment of farms and dairies supplying immunized milk for the exclusive use of children or adults showing evidences of tuberculosis. (5) Vaccination of pregnant cows to secure immunized products of conception. (6) The administration to tuberculosis patients of the whole blood of immunized animals, including serum and corpuscles. It had been shown that not only the serum but the other elements of the blood contained antibodies. They had perfected a technique by which the blood was rendered less disagreeable and more appetizing than in its natural form.

Fibroid Degeneration of the Appendix.—Dr. Robert T. Morris of New York read this paper in which he stated that fibroid degeneration of the appendix was an irritative lesion rather than an infective lesion. It might appear at any time during the life of an individual but was most frequent in middle life. It apparently belonged to an involution process which was normal in a way. The local symptoms consisted in an occasional twinge of pain in the region of the appendix, sometimes pain lasting for three or four days, but rarely a continuous pain. Pain was a symptom rather than tenderness. Two other definite signs associated with these were hypersensitiveness of the right group of lumbar ganglia, and, less noteworthy, distention of the ascending colon and cecum with gas. It was his assumption that hypersensitiveness of the right group of lumbar ganglia, associated with fibroid degeneration of the appendix, meant that the efferent impulse from a certain segment of the spinal cord related to the nerves of the appendix made greatest demonstration in the lumbar ganglia. When derangement of function was concerned they might assume that the efferent impulse disturbed the semi-lunar ganglia of the solar plexus and perhaps also the intimate ganglia of the bowel wall. At any rate derangement of the digestive apparatus occurred as a result of focal irritation at the appendix. The question of operation was a question of expediency. Many of these patients presented other stigmata of decline, and the gastrointestinal disturbances were relieved in part only by removal of the fibroid appendix. Other patients were relieved from gastrointestinal disturbances as soon as the fibroid appendix had been removed. It was his plan to give the patient a full explanation of the nature of the case and allow him to decide himself in regard to operation. Fibroid degeneration of the appendix was first described by Senn and by Ribbert, but these authors confined themselves to the anatomical features without describing the clinical significance of the condition. An irritative lesion of the appendix which brought a patient to the doctor's office more often than he was disturbed by an infective lesion of the appendix called for rather more attention than was commonly given the subject.

Radium in Gynecological Practice.—Dr. Walter B. Chase of Brooklyn read this paper in which he expressed the opinion held by many other operators, that surgical procedure had apparently reached the limit of palliative and curative power, and while holding to the principle that large operable growths belonged to the domain of surgery he also believed that surgery and radium were not incompatible, but rather reciprocal and supplemental. An inoperable cancer might be made operable within three to four weeks by the use of three or four thousand milligram-hours of radium. Radium therapy was based on prophylactic preoperative and post operative application. To insure the highest degree of efficiency its early use was imperative. The most favorable time for application was immediately subsequent to operation. Crossfire with radium greatly enhanced its power. Not infrequently burying the radium in malignant structures or placing it in the vagina was of the greatest importance. In uterine cancer the writer stated that he had used it continuously for ninety-six hours. Not only in malignancy had radium a field in gynecological practice, but its power to control uterine hemorrhage was worthy of trial and consideration. The author quoted from the annual report of the Radium Institute of London, in which, during the year 1914, 841 patients were treated showing the many favorable results that had occured in cancer from the use of radium and he also reported a number of cases from his own experience showing the palliative and curative effects of this agent.

The Application of Anociassociation to Obstetrics.—Dr. Carl Leslie Hoag read this paper in which he described Crile's method of administering nitrous-oxide oxygen together with a local anesthetic which had been used in surgery with success for the past three years. This method he had applied in obstetrics and found that it shortened the first stage of labor and rendered delivery practically painless. This method was so simple that it could be employed by the general practitioner and was free from the dangers that had been attributed to the "twilight sleep."

AMERICAN NEUROLOGICAL ASSOCIATION.

Forty-first Annual Meeting, Held in New York, May 6, 7, 8, 1915.

President, Dr. George W. Jacoby of New York.

(*Concluded from page 172.*)

Friday, May 7—Second Day.

The Study of Temporary Abnormal Mental States Conforming to Recognized Types of Psychoses.—Dr. Sidney I. Schwab of St. Louis read this paper, in which he said there were to be found running through the lives of most individuals who were characterized as normal, periods of mental reaction which presented to the inquirer many of the characteristics which were commonly met with in definitely outlined psychoses. These periods showed with great exactness all the symptomatological evidences upon which the diagnosis of clinical insanity might aptly be based. There were in addition maladjustments which in essence presented the common form of permanent psychosis. Many in-

stances commonly labeled neuroses were found after diligent study by one method or another to be something else. The class of individuals sketched seemed to fall very naturally into groups as follows: dementia præcox, depressive group, manic depressive group, the paranoid group, pseudo self-accusatory group, delusional group and the group termed inadequacy. The necessary conclusions, if this view was at all suggestive, was that an intimate study of this class of individuals would lead to an understanding of the maturer types of psychoses, give an opportunity for direct prophylaxis and the study of the physical factors concerned.

Dr. D. J. McCarthy of Philadelphia thought this paper of Dr. Schwab's was not only very suggestive but one of extreme practical value. The general tendency of the mind of the individual from childhood up, as he thought, was too often neglected. If the doctor happened to know the development and history of the child from infancy up much information would be given to him upon which he might form a prognosis.

Dr. E. E. Southard of Boston said this communication was very important. The subject had certainly been neglected by neurologists on account of being busy with other things and by alienists because they had no cases.

Dr. Joseph Collins of New York said that in the eleven thousand patients which had come into the Out-Patient Department of the Neurological Institute since its existence in the last five and a half years there had been about twenty-five hundred under the category to which Dr. Schwab had referred.

The Development and Operation of the Laws for Hospital Observation of Cases of Allied Mental Disease or Defect in Massachusetts.—Dr. Henry R. Stedman of Brookline, Mass., read this paper, stating that the advantages of hospital observation in criminal cases over the practice of occasional examination at the prison must be apparent to all. It was common to find no evidence of insanity until repeated and prolonged examinations had been made. To require by law a period of hospital examination in cases where insanity was pled as a defense tended to lessen the number of such pleas. Concealed delusions and feigning could be detected only with difficulty unless opportunity was given for careful trained observation. Although Maine and New Hampshire had had a law requiring hospital examination of criminals, in Massachusetts, since 1905, the law had applied to non-criminals as well. During the past five years 370 non-criminal persons had been sent by the courts for varying periods, usually 30, 60 or 90 days, for observation. Of these over 50 per cent. were pronounced insane and committed to State Hospitals. With the exception of those still under observation and eight who died, the remainder were discharged to their homes. The superintendent generally found the law very satisfactory. The judges also regarded the law favorably. Such laws should be widely adopted throughout the country.

Dr. E. E. Southard of Boston said that at the Psychiatric Hospital in Boston they had a large number of these cases and he had taken a personal interest in them. He thought there was no opposition to the law by any one in the State. Germane to this was the allied fact that the State Industrial Board had sent to the Psychiatric Institute all suspected traumatic psychoses. Dr. Southard thought it was the first time in the world where a fair, unprejudiced, unbiased study of these cases was made.

Dr. Walter Channing of Brookline, Mass., said it seemed to him it would be of the utmost value if we could have in this country some sort of national reorganization of all our laws relating to the admission of the insane to the hospitals. If, for instance, those laws that were good in Massachusetts could be adopted in other States. Nothing could do more for the prevention of insanity. Until something of the sort was done we should go on with our practice of admitting large numbers of persons who could be treated outside.

Saturday, May 8—Third Day.

A Case of Wilson's Disease—Progressive Lenticular Degeneration, with Pathological Findings.—Dr. Frederick Tilney of Brooklyn read this paper, which was prepared in collaboration with Dr. G. M. MacKenzie, Brooklyn, reporting a case presenting a typical syndrome of progressive lenticular degeneration, as described by Wilson. It ran a moderately acute course, terminating in death in fifteen months. The oustanding clinical features were the marked hypertonicity of the somatic musculature and the evidence of extreme toxicity. A preliminary report of the pathological findings in the brain was given and with this the histological findings of the spinal cord, liver, spleen, kidney, thymic remains, thyroid, heart, lungs and suprarenal bodies.

Dr. H. H. Hoppe of Cincinnati said that he had a case in a woman of 45 which presented quite a number of the features of Wilson's disease. There was hypertonicity associated with constant athetoid movements. The legs were constantly in a state of motion and the feet were inverted. There were no pathological changes in the reflexes, excepting that they were increased. The woman's mental state was practically normal, except that she was constantly in a state of rather pleasant frame of mind.

Dr. Alfred Reginald Allen of Philadelphia said that Wilson had so limited his disease, so exactly described what it is pathologically as well as clinically, that it would be very difficult to make a hard and fast diagnosis of uncomplicated Wilson's disease outside of the autopsy room.

Histopathological Findings in a Case of Landry's Paralysis; Demonstrated by Lantern Slides and Microphotographs.—Dr. E. D. Fisher of New York read this paper, reporting a case of a boy fifteen years of age who became suddenly ill, complaining of weakness in the lower extremities. After admission to St. Vincent's Hospital his condition became progressively worse until a complete paraplegia of the lower extremities developed. This was of the flaccid type. Within seven days the upper extremities became involved in the same manner. The muscles of all limbs became atrophied. Reaction of degeneration was present in the lower and marked quantitative and qualitative electrical changes in the upper extremities and shoulder muscles. There was also a partial dissociation of touch, pain and temperature sense in those extremities. Subjective sensory disturbances were a constant accompaniment. Toward the end of his illness most of the cranial nerves became involved. The bacteriological examination of the blood and spinal fluid was negative. The cytological examination of the spinal fluid was also negative. A slight rise in temperature marked the entire course of the disease. The patient died of asphyxiation after an illness of six weeks. The autopsy was performed by Dr. John H. Larkin and specimens of the cord and brain stem and sciatic nerve were prepared by him for examination. The histological examination reveals changes throughout these tissues. The spinal nerve roots and the sciatic show marked parenchymatous and interstitial changes with an infiltration in the perivascular and perineural lymph spaces of leucocytes, plasma cells and some gitter cells. The cells of the posterior horns at all levels of the cord show a central chromatolysis, especially marked in the cells of Clarke's column. Such type of cell degeneration is also evident throughout the bulb and pons. The cells of the motor neurons show in addition two other types of degeneration, namely: a swelling and coalescence of the Nissl bodies, a tygrosis with eccentric nuclei and staining very deeply and in some places an extensive cell vacuolization. Around these there are to be seen satellite cells which at times dip into the cell body. Their prolongations are visible and are retaining to some extent meshes of chromophilic bodies. The vessels and capillaries are engorged throughout and at times are seen to burst, producing hemorrhage into the neighboring tissues. Frequently we meet with capilary aneurisms and thrombi. Hemorrhages, rather minute and to all appearance recent, are present at all levels of the cord and brain stem, both in the gray and white matter. A marked glia proliferation is a feature throughout. At some levels of the cord an ependymitis of the central canal is present. In a word, we are dealing here with neuritic as well as a cellular involvement, the former being more pronounced. The cell changes of the central chromatolysis type are of a reactionary character due to remote influences in their neuraxone, while those of the tygriosis type speak for a primary cell involvement as a result of an inflammatory condition around and in the cells. The clinical aspect and the pathological changes that we find in cases of an acute ascending paralysis of the type of Landry point to an infectious process. Our case would show that both the infectious agent and its toxin are responsible for these changes. Which of the two are predominating is an

open question. The predominating type of pathological changes in Landry's paralysis is that characterized by inflammatory myelitic changes with very slight, if any, nerve changes. For this reason recent investigators are inclined to regard this disease as poliomyelitis. But in this affection we deal with a distinct etiological factor and are able to reproduce the characteristic pathological picture. In Landry's paralysis divers kinds of cocci and bacilli were found and the pathological picture was not uniform. We may, therefore, conclude that: 1. The clinical picture is the criterion of Landry's paralysis. 2. That pathologically there may be a purely cellular, or neuritic only, or a neuro-cellular involvement, and 3. That the time element is no criterion of the disease, since it may last from eight days to eight weeks.

Dr. Carl D. Camp of Ann Arbor stated that some time ago he reported a case of acute unilateral ascending paralysis which came to necropsy and in which were found in the peripheral nerves very much the same degenerative changes that were described here. At that time he also noted the abnormality of the anterior horn cells and regarded it as a phenomenon secondary to the changes in the nerve.

Dr. Israel Strauss of New York said that all know of cases of Landry's paralysis in which no pathological lesion could be discovered. At first when this disease was described we did not have at our disposal the technic described to-day. Since those cases were described other cases had been described and present distinct clinical features which render it possible that there could be acute ascending paralysis without very much in the way of microscopical lesion.

Observations on Hereditary Syphilis Affecting the Nervous System.—Dr. Carl D. Camp of Ann Arbor read this paper, in which he stated that syphilis is the most frequent cause of mental defectives. The diagnosis may sometimes be made by the peculiar clinical type which generally adheres to the type of Finkler under the title of infantile pseudo general paralysis. A certain proportion of cases of epilepsy were due to syphilis.

Dr. William W. Graves of St. Louis said that in an individual who did not present heretofore generally recognized signs of syphilis, such as Hutchinson's teeth, etc., the case at once has little or no suggestion of the possibility of being one of syphilis. In regard to the relation of epilepsy and congenital syphilis in his experience it was not a great factor. Neither was it a very great factor in those cases we call feeble-minded. One characteristic of the congenital syphilitic is early precocity. A thing Dr. Graves thought that was not made use of as much as it should be in our study of congenital syphilis was our failure to make family studies. The one characteristic of syphilitic infection was deviation from the type. If we used parents for standards in our studies of syphilis we would be impressed with the deviating characteristics of the entire individual. One needs to study the progeny of paretic and tabetic parents, and Dr. Graves was sure that anyone who would do this would not fail to be impressed with the deviating characteristics of the children of paretics and tabetics.

Circumscribed Purulent Meningitis Limited to Frontal Lobe; Due to Sinusitis.—Dr. Samuel Leopold of Philadelphia read this paper, reporting two cases of frontal sinus meningitis with necropsy. The first case, a boy of 14, gave a history of repeated colds in the head. Finally he developed a persistent frontal headache and swollen right eyelid. Operation revealed disease of the frontal sinus. Several days later he developed stupor with rigidity of the left lower limb, with some hemiparesis. Necropsy showed a purulent exudate beneath the dura and chiefly limited to right frontal lobe. The left frontal was diseased. The second case gave a history of influenza followed by meningitis. The chief symptoms were stupor alternating with delirium, slight rigidity of the neck and Kernig's sign. There were no localizing symptoms. Death occurred in 5 days. Necropsy revealed a similar limitation of the exudate as described in Case 1, over the upper surface of the one frontal lobe. Early operation was advised where this condition is suspected.

Dr. E. E. Southard of Boston said that some years ago he was doing work with experimental meningitis and tried to produce results like those seen in human cases, but he was never able to do so. A culture from one part would be sterile, in another part the true organism, and in another part many organisms. Various parts of the meninges had different resistance to infection. There was a tendency to healing in meningitis.

Meningitis Sympathica.—Dr. Israel Strauss of New York read this paper, stating that meningitis sympathica was the name given to those changes which occurred in the cerebrospinal fluid when an inflammation was present in the neighborhood of the meninges. The pressure of the fluid was greatly increased and might reach as high as 400 mm. There was an increase in the cellular elements, the cells generally being polynuclear leucocytes. The fluid was sterile. There might be no symptoms of meningitis, but very often there was considerable neck rigidity and Kernig's symptom was present in varying intensity. One of the most frequent causes of the condition was brain abscess, especially where there had been a previous otitis. It might also be present in patients where there was an inflammation of the accessory sinuses of the cranium or of the structures adjacent to it. We frequently met with intracranial inflammatory conditions where there was no evidence of meningeal irritation, but when meningitis sympathica was present it aided us both in the diagnosis and treatment.

A Case of Central and Peripheral Neuro-Fibromatosis (von Recklinghausen's Disease). — Drs. Peter Bassoe and Frank Nuzum of Chicago presented this paper, narrating the case of a boy of 15 years at death. From the age of 4 years he had had attacks once a year, lasting two weeks to three months, of pain in the back near the right scapula. Dragging of the left foot was noted after the first attack. At 10 years he had eight eye muscle operations. A lump on the left side of the neck was noted three years before his death, a pelvic tumor three months before death. The findings on examination suggested basal brain tumor and cord tumor. Several subcutaneous nodules led to a correct clinical diagnosis. Necropsy showed large fibromata in both cerebello-pontile angles. Large tumor of cauda equina. Numerous small tumors on various cranial and spinal nerves, also tumors on nerve roots in places invading the cord and a large tumor outside of the rectum.

Mental Disturbances in the Feeble-Minded.—Dr. William N. Bullard of Boston contributed this paper in which he said that the character of the attacks of mental disturbance in the feeble-minded was quite distinctive. In persons who showed only the ordinary conditions of feeble-mindedness or idiocy there occurred without any exciting cause sufficient under ordinary conditions to produce such an effect, a sudden outburst of violence or temper. They scream, strike, kick, bite, destroy clothing and furniture and often require forcible restraint; they are obscene and profane. The attack lasts only one or a few days. There are usually prodromal symptoms such as listlessness, indifference and unusual actions.

Officers.—The following officers were chosen for 1915-1916: *President*, Dr. L. F. Barker, Baltimore; *First Vice-President*, Dr. H. H. Hoppe, Cincinnati; *Second Vice-President*, Dr. J. J. Thomas, Boston; *Secretary-Treasurer*, Dr. Alfred Reginald Allen, Philadelphia.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held January 14, 1915.

Dr. Walter Lester Carr in the Chair.

Report of Four Cases of Hemorrhagic Disease in the New-Born Treated by Horse Serum. — Dr. Abraham Hymanson reported these cases which occurred at the Jewish Maternity Hospital. These infants all gave a negative family history and showed the symptoms usually presented by hemorrhagic disease in the new-born, namely, blood in the stools, vomiting of blood, and purpuric spots. In all of these cases the children were in a serious state of collapse when the treatment was instituted. This consisted of the subcutaneous injection of 12 c.c. of horse serum, followed by a second dose of the same quanitity at the end of twelve hours, and a third dose if it was indicated. In one of the cases a dose of 15 c.c. of the horse serum was administered. In three out of the four cases the bleeding ceased in a short time after the treatment was instituted, while in the fourth instance there was a fatal outcome, though the injection of human blood, that of the mother, was resorted to when the horse serum failed to produce the desired effect. The horse serum had been furnished by the Department of Health. Dr. Hymanson concluded as follows: (1) From an observation of the cases

it seemed that the coagulation time of the blood was somewhat delayed in the condition under discussion. (2.) As there was always a difficulty in obtaining human blood or fresh blood serum, fresh horse or rabbit serum would serve the purpose just as well. (3.) In the newly born infant, where the bleeding was not spurious, the horse serum should be administered early and repeatedly until the bleeding ceased. (4.) The injurious effect that was caused by foreign serum had been greatly exaggerated. Serum sickness was, as a rule, a very mild affection, lasting only a few days. Serum death was a rare occurrence. Dr. Probasco had claimed that there was only one death in 25,000 injections of diphtheria antitoxin. It had been shown that nearly all deaths from antitoxin occurred in patients during adolescence or in asthmatic adults.

Dr. Henry Dwight Chapin said that in two cases of hemorrhagic disease in the newborn that had come under his observation the horse serum had been tried, but had not been effective, and that they had been compelled to fall back on human blood serum. Dr. Chapin asked Dr. Hymanson if he had considered giving the diphtheria antitoxin as a means of administering the horse serum, and if he had used the human blood serum, and, if so, with what success.

Dr. L. E. La Fetra said that it was well known that the use of human blood would check most hemorrhages of the class under discussion, but the use of whole blood as proposed by Dr. Schloss was much simpler. By Dr. Lindeman's method it was a very simple matter to withdraw ten, fifteen, or twenty c.c. of blood from the mother or father and inject it into the back of the baby. By this method one did not have to wait as was necessary when blood serum was used. Using whole blood he had been successful in about three-fourths of the cases. The success of the procedure was dependent upon the etiology of the hemorrhage; hemorrhage due to general sepsis was not so amenable to treatment as when due to some other causes. In his opinion this method of Dr. Schloss was the best and quickest one available for this purpose at the present time.

Dr. Fenton B. Turck said he would like to say something on the experimental side of this subject which had a very marked bearing on what the essayist had presented. He had been making comparative tests of the intestinal bacteria on homologous sera and had found that in young children bacterial migration occurred in the same manner as had been observed in experiments on young animals. The bacteria passed from the intestines very readily into the submucous tissue of the intestinal wall along the entire alimentary tract. The bacteria passed between the cells at the base of the villi, crossing the muscularis mucosa into the submucous areolar tissue, the "zona transformans," and were here destroyed. The antiferment in the serum was found to be reduced by this process. Previously they had found that the administration of chloroform reduced the antiferments in the blood, which was the same phenomena which they now found occurred when the intestinal bacteria entered the submucous tissue and came into contact with the sera. It was found that when intestinal bacteria (*B. coli*) were fed to pregnant animals the bacteria would pass into the fetus and cause reduction of the antiferments, resulting in premature births, with hemorrhages and death of the newborn. The study of these experiments gave some suggestion as to treatment. When there was a reduction of the antiferments in the blood it was unnecessary to theorize about the absorption of toxins, for it was not shown that toxins were formed. The rapidly destructive power was the result of the reduction of the antiferments permitting destruction by autolysis to take place. This phenomena could be demonstrated *in vitro* as *in viro*. The experiments undertaken in the production of hemorrhagic diseases were important and seemed to prove the value of supplying the deficiency of the antiferment in the sera by the addition of fresh blood. To the specialists in children's diseases there was an exceptional opportunity of making observations in these cases that were even better than animal experiments and some of the points had been well shown to-night.

Dr. Abraham Hymanson, in closing the discussion, said that in reply to Dr. Chapin's questions with reference to the use of diphtheria antitoxin in these hemorrhagic conditions, theoretically it would amount to the same thing whether they used the diphtheria antitoxin or normal horse serum, provided it were fresh. The diphtheria antitoxin also contained the antibodies in addition to the other active elements of the serum and these ought not to hurt the baby. He quite agreed with Dr. Le Fetra in what he had said of the advantages of giving fresh human blood, but the trouble was that one could not always get a suitable donor in a short space of time. He cited an instance showing that the father was not always willing in such emergencies to give his blood. He had used the Board of Health serum and it had worked marvelously well, though the number of cases that he had treated thus far was not very great. Dr. Hymanson said he was not prepared to speak of the experimental side of the work as Dr. Turck had done, but he was glad to learn that it furnished some justification for the clinical results that had been obtained. As to the matter of the placental serum, that could be used with ease in the maternity hospitals by allowing the blood from the cord to run into sterile flasks, centrifuging, and sealing with a few drops of chloroform. (The chloroform was used as a protecting layer for the serum.) Dr. Franz of Graz claimed that this could be kept as long as four months, but here one must have the Wassermann test to exclude syphilis.

A Study of Certain Aspects of Epilepsy Compared with the Emotional Life and Impulsive Movements of the Infant.—Dr. L. Pierce Clark presented this communication, in which he first recalled that in previous studies of the epileptic constitution and in a psychological study of the meaning of the fit in epilepsy, it had been shown that the fit was a libidinous outlet for the infantile unconscious. The loss of consciousness was thus shown to be due to the insistent demands for expression of the unconscious, transferring the older conception from a negative postulate to a positive dynamic one. In its simplest and crudest form the nucleus of the unconscious striving was a desire on the part of the individual epileptic, not only to return to a state of infancy with the parent, but it really contained a motive for the epileptic to gain the life before birth as symbolized in the idea of life within the mother. In a measure this hypothesis supported by clinical observations seemed to be a sufficient psychological explanation of the fit so far as the loss of consciousness was concerned, which was, after all, the real nucleus of the epileptic attack. There were other questions, however, which arose for solution. One of these was the interpretation of the convulsive movements of the seizure. The physical correlates of the convulsive spasms of the fit showed a very close parallel of movements in intrauterine life and in infancy, and under certain states of excitation produced acts which were point to point identical to those seen in *grand mal* epilepsy. Probably the convulsive movements in all the varied types of epileptic fits from the most purposeful or voluntary to those of the severe grades were drawn from the different developmental levels of child activities. Dr. Clark then discussed the significance of the epileptic cry which he said most observers were agreed was more than a mere mechanical expulsion of expiratory air from the thorax as a sequence of tonic spasm. This cry of the epileptic could be compared with the pleasure-displeasure cry of infants which was associated with tonic-clonic movements of the arms and legs. There was also an analogy in certain movements in the epileptic with displeasure movements in the infant, such as deflection of the head to one side, a turning away movement; drawing of the mouth at one side, then upward and backward, and the quadrangular or squarely opened mouth, which Darwin dwelt upon as an extreme expression of childish rage. It was interesting to observe the *tedium vitae* in the infant and the epileptic alike; the lack-luster eye, indolent movements, cessation of spontaneous interest, a falling of the countenance, and a paler complexion—all had long been considered as heralds of a *grand mal* attack. The great importance of a large amount of sleep in the epileptic was comparable with that required by the infant, while interruptions of sleep in both infant and epileptics were alike disastrous to well being or good temper. Impulsive and incoordinate movements of infancy during sleep and during fetal life had a parallel in the adult in whom such bizarre movements were sometimes seen during sleep and particularly in the epileptic. A study of the infantile poses and postures assumed by epileptics during sleep should be studied more carefully as they threw an interesting side light upon the somatic and psychic infantilism of epilepsy. Some of the depressors of these impulsive movements were deep, quiet, sleep, satiation by food, while duplication of the intrauterine state by the warm bath acted as an accelerator. It was striking that both infants

and epileptics were little fatigued by the most intense and persistent impulsions, which spoke strongly for the unconscious motivation in the activities of both. In conclusion Dr. Clark submitted that they were justified in considering that the essential nucleus of the epileptic fit was a libidinous one; that it consisted in an infantile unconscious striving of pleasure-displeasure pursuit ending in the final goal of an intrauterine life, attended by a loss of consciousness and convulsions; that the convulsion was expressed through the lower spinal centers in inducing crude and impulsive movements; that a study of the degree of development of unconscious infantile striving in the psychosexual sphere of the libido, the desire for the fetal uterine state of *allmacht*, was paralleled by the kind and character of impulsive movements found in this infantile period of neuromuscular development. Therefore, the two main settings in the epileptic fit, unconsciousness and convulsions, were psychically and physically correlated, and lastly that epilepsy was in its essential pathogenesis an error or arrest of this fundamental elaboration or development of the psychosexual libido. The essential pathogenesis of the disorder was still to be attacked, but the author believed that such studies as the one presented here and as were elsewhere reported narrowed the gap between such supposed causes of epilepsy as inherited psychic traits and somatic structural anomalies which did not permit of proper psychosexual development into the normal adult. It also pointed the way by which therapeutics might advance along the broadest biological lines of educational and moral treatment.

Dr. JOHN T. MACCURDY said that the underlying wish in the epileptic to return to a state of rest equivalent to that which the individual enjoyed in fetal life might seem a bizarre conception, but from his experience and that of others with the insane it had to be regarded as a frequent type of unconscious wish that came often to open expression in psychoses. From that standpoint therefore he felt fully in accord with Dr. Clark. He then spoke of the importance of the comparison which Dr. Clark had made between the suckling and the epileptic in reference to convulsive movements. On the basis of this identity he outlined a possible physiological theory for the origin of the convulsive movements, on the supposition that the mere loss of conscious control might set all the voluntary muscles into incoordinate motion.

Dr. J. VICTOR HABERMAN said that it seemed to him that the logic of Dr. Clark's paper was also unconscious. If the initial cry of the epileptic could be sufficiently explained by the sudden contraction of the thorax forcibly expelling the air through the larynx, why should one not accept this explanation instead of a far less logical one? He had noticed that in all their writings, the Freudians gave no proof of their theories; they assumed certain things, left it at that, and then asked others to accept their opinion. Dr. Haberman asked whether the epileptic voice, which Dr. Clark had described some years ago, was also a cry of the libido; also whether the convulsions in renal disease and in brain tumors were the expression of the libido? How did Dr. Clark explain the fact that in many cases of epilepsy one found an actual pathological condition? Some believed, and it had even been expressed by Freudists, that all idiopathic epilepsy was due to pathological (organic) conditions of the brain. How did Dr. Clark correlate these facts?

Dr. ISRAEL STRAUSS said that he rarely spoke or discussed a paper that dealt with a subject treated from the Freudian standpoint because it was impossible to influence anyone who had taken that position. He had much sympathy with Freud's theories, but he had always thought that the psychanalysis of Freud applied to neuroses, and epilepsy was not a neurosis. A study of the brains of epileptics had shown many lesions, and Dr. Clark himself had described changes in the ganglion cells in epilepsy and so it seemed that to look upon this disease as a neurosis one would have to revise his conception of the pathology relating to it.

Dr. L. PIERCE CLARK said he regretted the facetious element in the discussion. It was quite true that the logic and the line of reasoning in determining a psychological basis for unconsciousness must entirely concern the unconscious and if the logic and the motive of the mechanism were in accord, so much the better. The fact that the epileptic cry was not satisfactorily explained by any simple mechanical principle, and was so stated in any number of textbooks on epilepsy, urged them toward finding some other elements as well as the psychical to account for it and thus make clearer this one phenomena which was so peculiarly unique to the epileptic state. It could not be reproduced by imitation, nor was it present in any other phase of disease. They now had a very good explanation of the voice sign. The essential defect in epilepsy was one of the primary instincts. That being the case, they would expect the condition to show in later life as an affective emotional defect in the epileptic mentality, which was the case. If this were granted, they would quite expect that there would be an essential incompleteness of emotional expression in epilepsy. Therefore, they found that as a class epileptics were neither good musicians nor had beautiful voices. Of course, it was absurd to push the epileptic mechanism to explain all convulsions occurring in other disorders purely as symptoms, such as those occurring in renal disease or brain tumor. The equal presence and absence of any histological lesion in the epileptic brain would make one, on the face of that statement, throw aside any lesion as being essentially a causative factor. They must look upon such brain lesions when present as a result of the disorder and not its cause. While many had observed a fairly close relation between certain diseases of the motor cortex and the epileptic convulsion, no one had been so bold as to push the law of psychophysical parallelism to the point of making such lesions in the cortex the cause of loss of consciousness as seen in the epileptic attack. Inasmuch as the latter symptom was the one essential factor in epilepsy it was necessary for them to bring into play a defect in some fundamental principle in life which should be as broadly significant in motive as that which underlay life itself. This was what the speaker had attempted to do. In point of fact, one might say that all the organic lesions in the epileptic brain were but precipitating factors in lowering mental tension or continuing the same, thus permitting certain morbid phenomena in the instinctive life to have their play as shown in the fit. While the formulation of the principles which he had brought forward might undergo more or less modification, it was his belief that he had outlined a rational and fundamental plan for understanding both the loss of consciousness and the convulsions of epilepsy. What might be the precipitating causes of the underlying defect of the epileptic constitution which permitted individuals to have seizures was still a question demanding solution.

The Present Conception of Chorea. — Dr. ISRAEL STRAUSS read this paper, which he prefaced by referring to the many different hypotheses that had been advanced to account for chorea. He stated that it had been attributed to a hereditary tendency to neuropathic taint, fright, and excitement. The more probable theory was that these were but predisposing causes, the disease itself being of infectious origin. The purpose of this paper was simply to weigh and discuss these different views. The relation of rheumatism to chorea had been noted and the suggestion had been advanced that they might be due to the same agent, or that the one stood in a causative relation to the other. Possibly chorea was a metarheumatic condition, just as tabes and paresis were parasyphilitic affections. Authorities were by no means in accord with regard to the embolic theory. One authority stated that 56 out of every 63 cases of chorea gave a history of rheumatism and Thayer stated that 21.6 per cent. of choreics had had rheumatism. To settle this question satisfactorily, the etiology would have to be discovered in both conditions. There was evidence of the presence of the streptococcus in most cases of polyarthritis. Diplococci and staphylococcus pyogenes aureus had been found in choreics and much biological work had been done by the different methods, complement fixation, ærobic, and anærobic methods, and the results differed widely. Chorea had been known to follow typhoid fever, malnutrition, syphilis, the abuse of alcohol, etc. It was a disease of early life and occurred most frequently between the ages of six and fifteen years. It was more apt to occur in wet cold seasons. It was frequently febrile in the early stages and gave evidence of endocarditis. The fatal cases showed the rugæ of endocarditis. What influence the cortex exerted was unknown. In fatal cases the brain lesions were those of acute encephalitis and this brought up the question to what extent such lesions were present in the ordinary cases that went on to recovery. The probability was that this would never be known until some case of moderate chorea died suddenly and an autopsy was obtained. In the present state of their knowledge the

only conclusion that was justifiable was that chorea was probably of infectious origin, but the data at present was altogether insufficient to decide the nature of the infection.

Dr. L. E. La Fetra said he had come expecting a very different expression of opinion on the subject of chorea and was prepared to disagree, but, on the contrary, he quite agreed with what he had heard. It seemed that chorea must be considered as closely related to polyarthritis and must be considered as due to some kind of bacterial infection in the vast majority of cases. There were two points to which he wished to call attention: First, in Bellevue Hospital they had made a number of studies of the blood in chorea, and in two of these the streptococcus viridans was found in the blood. Complement deviation tests by Dr. Hoobler were found positive in two other cases. In the second place, it had been observed that children who had just recovered from polyarthritis or acute endocarditis frequently developed chorea while still in bed. When the influences that were generally given as exciting causes of chorea were absent, when there was no fright, no malnutrition, no exictement, nothing in the way of nervous shock to account for the development of the chorea, one might feel quite positive that in the majority of cases chorea was an infectious disease. On the other hand, there were some cases that followed so quickly upon fright and nervous shock that it would seem probable that there were cases that had a basis other than that of infection.

Dr. J. Victor Haberman said that no mention had been made of psychic chorea. He recalled a striking case that came to Dr. Starr's clinic some years ago. This patient had a chorea so apparently typical that Dr. Starr was about to show her to the students. For the relief of a headache of which she complained she was taken aside and treated by hypnosis. On awakening, not only had the headache disappeared but the entire chorea. After this Dr. Haberman treated a large number of choreics coming to the clinic psychically and found that in some the chorea disappeared at once; in others after a few treatments. In these cases the disease could not have been rheumatic chorea. In studying a still larger series he had come to the conclusion that psychic chorea was not uncommon, and that many, if not most, of the cases lasting over three months were of this nature; also, that many of the recurring attacks in neurotic and hysterical children who might have had a real chorea in the beginning were psychogenic. The child was on the watch for a new attack and so got it. These cases were all strongly amenable to psychic therapy. There was no way of differentiating the rheumatic from the psychogenic save by the result of treatment. Another series of cases was due to congenital syphilis. Millian in France and Nonne in Germany had called attention to these cases; the former believed that he had found lues so frequently in the heredity of choreic cases that he thought chorea itself must be a manifestation of congenital lues. Few, however, had accepted his view. Nevertheless, there were cases certainly due to this factor. Dr. Haberman cited the case of a child whom he had recently treated who had had chorea for three years and been treated by a number of physicians, none of whom thought of associating the chorea with congenital lues, though the mother gave a positive Wassermann reaction. Antiluetic treatment speedily cured the chorea.

Dr. Henry Dwight Chapin said that Dr. Roger, the French clinician, had studied the relationship of rheumatism, endocarditis, and chorea many years ago, and had come to the conclusion that they presented the same underlying pathological condition, and it really seemed that up to the present time they had not gotten much beyond his view. It seemed undoubtedly that they were all of infectious origin. Where one of the three conditions was found one was liable to meet the others.

Dr. Henry Koplik called attention to the importance of seeing these cases of chorea through years, for it might be said of chorea "once a choreic always a choreic." Seeing the heart gradually becoming worse and worse led to but one conclusion, and that was that the poison causing the chorea was producing the endocarditis. The way in which the term rheumatism was used to-day was most unfortunate; it was much like the former use of the term "malaria." It was probable that the poison causing polyarthritis was closely allied to the one that produced endocarditis and chorea. The question was whether the habit movements were the result of or a continuance of a condition produced by infection. The cases which Dr. Haberman had spoken of as controlled by hypnotism could not, of course, be due to the same etiology as that associated with cases supposed to be due to infection. In many cases in which the blood cultures of cases of chorea had been examined the technique might have been faulty; in others a mixed infection might have been found. In several cases of chorea which he had had examined in this way nothing had been found in the blood. It was quite possible that the streptococcus might accompany the true organism, just as it might be found associated with the Klebs Löffler bacillus.

Dr. Elias H. Bartley of Brooklyn stated that they had made cultures at the Long Island College Hospital of three or four cases of well defined chorea and in none had they found any organism. This was not a large number of cases and it did not lead to the conclusion that there was no infection, but it did mean that the particular organism which had been mentioned had not been found; if this organism was the cause of the disease it must be constantly found in the disease, and as it was not found to be constant it could not be regarded as the cause of chorea.

Dr. Strauss, in closing the discussion, said he quite agreed with Dr. Koplik that it was unfortunate to use the term rheumatism as was done, since no two or three men agreed as to its meaning. With regard to polyarthritis and chorea, they could not say that the streptococcus viridans was the agent producing these affections. Dr. Libman's work at Mount Sinai Hospital was such that they could not say that he was incompetent to isolate this organism if it was in the blood, yet they had not succeeded in isolating it from the blood in chorea though they had made cultures ærobically and anærobically. Personally he did not believe that if the streptococcus viridans was there it would have escaped notice. Another point in regard to the relationship of rheumatism and chorea—in chorea one did not get good results from the use of the salicylates; the results were not those obtained in polyarthritis. On the other hand they had tried neosalvarsan in chorea and sometimes with surprisingly good results. This suggested that a protozoon might be involved. They had no right to say that because rheumatism occurred and was followed by chorea that the latter was due to the same cause as the former, neither could they say that because endocarditis had been found in 21 per cent. of the cases of chorea that the endocarditis and the chorea were due to the same cause. When one had a severe case of chorea insaniens, he could not, as a rule, save it no matter what was done, and one might find an acute parenchymatous nephritis, endocarditis, or even acute encephalitis, and he could not say that these cases were due to infection always. Therefore, though they might say that chorea appeared in association with and followed other diseases which were due to infection, they were not justified at present in any more definite statement of its etiology.

Acrocephalosyndactylia. — M. Bertolotti and G. B. Trotti report a case of this condition which was first described by Apert in 1896. It is a congenital malformation characterized by a pointed shape of the top of the cranium associated with a symmetrical syndactylia of the four extremities.—*Riforma Medica.*

Congenital Cerebellar Ataxia.—J. M. de Villaverde describes this condition as one in which the ataxic symptoms are perceived as soon as the infant begins to creep or walk, and diminish gradually in their intensity to disappear eventually entirely or to a great extent. The condition must be differentiated from the ataxias of Friedreich and of Marie.—*Revista Clínica de Madrid.*

Intestinal Motility and Tonicity as Affected by Intestinal Contents.—G. Ollino has studied the effects of certain substances found in the intestinal contents upon the tonicity and motility of the intestine under normal and pathological conditions. She found that starch diminishes motility following a period of spastic immobility. Peptone excites motility, and urea in addition excites tonicity. Creatinine diminishes motility, while guanine excites both tonicity and motility. Xanthine increases tonicity but diminishes motility. Sulphureted hydrogen in small doses increases the amplitude but diminishes the frequency of the intestinal movements. Indol diminishes motility and produces intercurrent spasms, while scatol and mercaptan diminish motility. Tryptophan diminishes tonicity, the fecal fats excite motility, and the soaps and putrescin produce a spastic hypertonia.—*Riforma Medica.*

THE BONE GRAFT WEDGE IN THE TREATMENT OF HABITUAL DISLOCATION OF THE PATELLA.

By FRED H. ALBEE, M.D., F.A.C.S.,

NEW YORK,

PROFESSOR OF ORTHOPEDIC SURGERY, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND UNIVERSITY OF VERMONT

THE usual direction of congenital or habitual dislocation of the patella is outward, and the external condyle is often found to be on a horizontal plane much below that of the internal condyle, thus giving the appearance of rotation of the lower end of the femur, so that the external condyle is relatively further back and the internal condyle farther forward than is normal.

When the leg is extended, the patella usually takes its normal position between the condyles, but upon flexion is found to be displaced outward and even to lay over the external condyle or somewhat external to it.

Various methods have been devised to correct this displacement, but of the procedures which have been practised by the author, those where correction was attempted by using the soft tissues have been far less successful in securing permanent control than those where the control was attempted by furnishing bony obstruction to redislocation.

Krogius[1] reported two cases (one double) in which it was evident that the patella was drawn outward by the tense outer portion of the capsule against which the relaxed and stretched inner portion offered but weak resistance. He devised the following operation for controlling the displacement:

The first step is the approach to the knee by Kocher's incision. Second, an incision is made, extending from slightly above the patella down a few inches in front of its outer edge to the insertion of the ligamentum patellæ through the iliotibial band, tendinous expansion of the vastus externus, and fibrous capsular wall. Third, the formation of a bridge-shaped flap on the inner side of the patella, connecting below with the tendinous expansion of the vastus internus and fibrous capsule, and above with muscle and fascia. Fourth, the transplantation of the flap, left attached at both sides, across the patella into the gap at its outer edge.

In the first case, after 6 months, the patella again began to slip outward, although complete dislocation did not occur. In the second case, the result was perfect after three months.

Outward dislocation of the patella may be the result of direct violence applied to the inner edge of the patella, but quite as often follows sudden muscular action. Knockknee, undue laxity of the ligaments, especially of the capsular and more particularly a deficiency of the external lateral ridge of the external condyle, all predispose not only to the occurrence but to the recurrence of the disability. A sudden muscular contraction with the leg extended or in midflexion, especially if the knee is inverted and the foot and leg are everted, is sufficient cause to produce displacement. Eversion of the leg brings the insertion of the ligament further out and affords a straighter pull for the extensor muscles. Reduction is generally easy.

The advice of the textbooks is to extend the knee, fully flex the thigh to relax the rectus, manipulate the kneecap by pushing it medialwards, at the same time correcting any rotation. The quadriceps with the knee extended may be pulled down to aid relaxation. If these manipulations fail, they may often be successful with the joint in slight flexion instead of extension.

Recurrence may happen only occasionally, usually unexpectedly, in the course of flexion, or it may occur very frequently, the patient learning to replace it himself. It means, in time, a relaxed, weakened, and uncertain joint. The recurrence may be relieved by a knee cap or by a bandage. As a rule, the annoyance is so great that something more radical must be done.

One operative procedure consists in reefing the medial side of the capsule, with or without opening the joint. Another consists in transplanting the insertion of the patellar ligament medialwards. These operations have sometimes been performed with good results, according to Whitlock, but he offers as a third method that of reinforcing the patellar ligament by grafting the tendon of the gracilis into it (Tenney[2]).

Dumferline describes a technique which he has used successfully. He takes a semilunar flap of skin and fascia from the medial and posterior surfaces of the knee, far enough back to enable him to reach the tendons of the semi-tendinosus muscle; the base of the flap crosses the line of the patella and the patellar ligament. The semitendinosus muscle is dissected as low as possible. The patellar ligament is split, a portion being turned up to be sutured to the cut end of the tendon of the semitendinosus. The medial portion of the capsule and the fascia are then plicated with several sutures, chromic catgut being used for both tendon and capsule.

Whitlock's method consists of turning forward a long horseshoe shaped flap of skin and fascia, with its base in front and its apex reaching backward to the line of the medial hamstrings, the base corresponding with the line of the medial margins of the patella and the patellar ligament. The ligamentum patellæ is exposed in its course for about three-fourths of an inch by dividing the thin capsular fascia overlapping its anterior surface, and

a thin Kocher fenestrated blunt dissector is thrust through the ligament from behind forward so as to separate the fibers as near its middle as possible, making a space of half an inch vertically. This is done without entering the general synovial

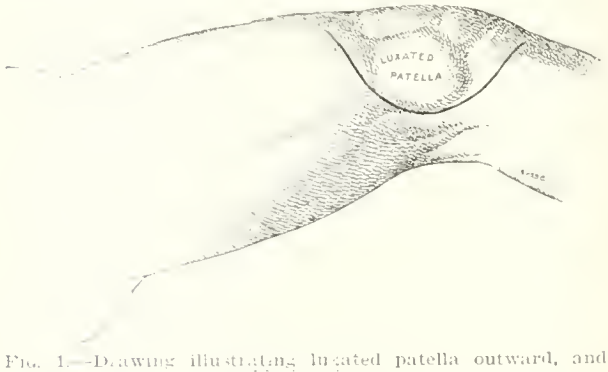

Fig. 1.—Drawing illustrating luxated patella outward, and skin incision.

cavity of the joint. The ligament is then split for a space of half an inch or more and prepared to receive the end of the gracilis tendon. This tendon is found by taking the sartorius muscle as a guide; the fascial attachment of the sartorius is divided above and posteriorly so that its edge may be thrown forward. The slim tendon of the gracilis is then seen lying proximal to that of the semitendinosus, and parallel with it are some vessels and a nerve which should be avoided. The gracilis tendon is isolated and divided as near its tibial attachment as possible. It is brought forward and threaded through the fenestrated director and passed through the patellar ligament, and is sutured with chromic catgut. Whitlock states that the gracilis was chosen partly because of its superficial position and its very long and supple tendon, but mainly because it is primarily an adductor in its action and innervation, being supplied by the obturator nerve. It is a less important flexor of the knee than the semitendinosus. The altered position of the transplanted tendon acts as a tie, fixing the ligamentum patellæ and preventing the passage of the patella outwards during full extension of the knee, while it tends also to rotate the joint medialwards. In cases in which there is a large amount of flaccidity of the capsule of the tendon, transplantation is fortified by reefing the capsule. Goldthwait[4] reports eleven cases operated upon for dislocation of the patella. Through a 5-inch incision, beginning at the tubercle of the tibia, the patellar tendon was exposed and split into halves. The outer half was freed from its attachment to the tubercle and drawn inward under the

Fig. 2.—A, indicates the normal size and anterior prominence of the external femoral condyle. B, indicates the flattened external condyle with a consequent luxation of the patella outward. C, indicates anterior lifting of the condyle to block the recurrence of the luxation of the patella with the wedge graft (dark area) in position.

remaining half, and sutured securely to the periosteum, together with the expansion of the tendon of the sartorius muscle at the inner side of the anterior surface of the tibia. A number of these cases recurred after the operation.

Murphy[5] reports his method of dealing with congenital luxation of the patella, which consists of exposing the joint freely through two longitudinal incisions, one on each side of the patella, and turning the patella with its attached ligamentum pa-

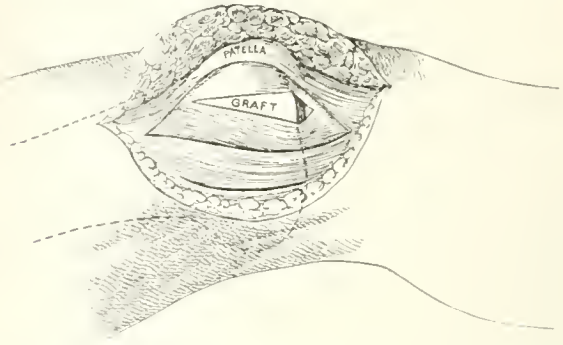

Fig. 3.—Operation for outward dislocation of the patella, showing shape of graft in position, lifting anterior portion of external condyle to block the recurrence of the dislocation.

tellæ to one side. With a broad gauge to correspond to the under surface of the patella, a segment of bone lying between the condyles is removed to deepen this intercondylar groove. A flap of fascia and fat is then turned in from above and sutured over this denuded bone area to prevent ankylosis of the patella to the femur. The patella is placed in position, resting on this fascia flap, and the inner portion of the fibrous capsule is drawn over the patella and sutured to its fibrous covering.

The extent of trauma to the joint surfaces would indicate possibility of adhesions and limitation of joint motion, and the absorption of the fascia fat flap covering in the incised bone area would also tend to cause adhesions and limitation of joint function.

Graser[6] presents his method, and reports several cases in which the outer condyle of the femur stood considerably further backward than the inner condyle when the leg was rotated outward. He effected a cure of the dislocation by performing a supracondyloid osteotomy of the femur and twisting the condyles so as to bring the outer portion forward and the inner condyle farther backward. This procedure carries forward the insertion of the ligamentum patellæ or upper end of the tibia with the outer condyle of the femur, and thus loses much of

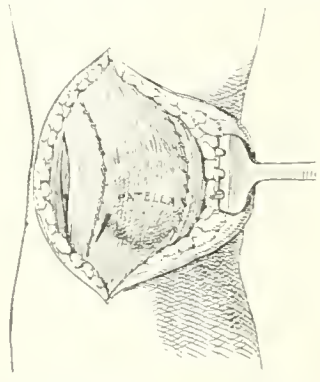

Fig. 4.—Patella fixed in position by wedge graft under external condyle and plicating sutures.

its potency. He recommends the procedure only when the posterior position of the outer condyle is marked.

The Author's Operation for Habitual or Congenital Dislocation of the Patella.—From the mul-

tiplicity of methods devised for the correction of this deformity, particularly those procedures having to do with the soft parts as a means for correction of dislocated patellæ, also from the case reports following such operations, it can be safely concluded that no method has proved universally satisfactory. Many of the patellæ have become redisplaced after varying periods of time following soft tissue operations for this fixation, as might reasonably be expected. Grafted soft tissue, whether it be ligament, fascia, or periosteum, will withstand but little constant strain and will gradually pull out if any great amount of traction is placed upon it. The most secure anchorage for tendons, fascia, or ligaments is through bone structure, and even then unless great care is exercised and the ligament itself be made to unite with the bone to which it is secured, independently of the suturing material, one cannot be assured that the new anchorage will remain secure. Any foreign material sutured into bone, where sufficient strain is placed upon it, will gradually pull through by its own destructive action.

On account of the failures reported by the various operators using different methods the author has devised a method which, from his experience with its use, appeals very strongly as a most rational and trustworthy means of permanently restoring the displaced patella without interfering with joint function, or offering any appreciable chance for failure. Instead of attempting to rectify the deformity by a complicated procedure or subjecting the joint to damage, a simple change of the architecture of the outer condyle of the femur suffices.

A semilunar skin incision is made to the outer side of the patella sufficiently long to reach below the tibial tubercle and to above the external condyle. Without unduly disturbing the underlying joint structures, the external condyle is incised with a broad thin osteotome on its external surface, making a bone incision of from 1½ to 2 inches in length, and about ½ to ¾ inch below its anterior articulating surface, and nearly in line with the long axis of the femur. This bone incision allows the anterior surface of the external condyle to be raised to a plane above the internal condyle, by producing a greenstick fracture near the intercondylar groove, the object being to place a permanent and rigid obstacle in the way of the outward displacement of the patella.

When the anterior segment of the external condyle has been pried forward sufficiently to demonstrate its obstructing effect, the width of the bone gap thus formed is measured with calipers and a section of bone sufficiently large to fill this cuneiform gap is removed from the crest of the tibia through the lower portion of the same skin wound extended below the tubercle. This bone-graft wedge can be very easily and quickly procured by the use of the motor saw. Before the graft is removed, it is drilled obliquely in one or two places by the motor drill, so that it may be pinned to the under portion of the external condyle when put into its place. Dowel pins, made from an additional portion of the bone removed from the crest of the tibia at the time the graft is obtained, are rounded by the author's motor lathe to fit the drill holes in the graft.

The cancellous structure of the condyle receives the pins easily when they are driven into place; or the motor drill can again be inserted into the holes already made in the graft and continue them into the external condyle. The ligaments and tendinous expansions are sutured over the graft, thus holding the lifted portion of the condyle securely by kangaroo-tendon. The skin wound is closed by a continuous mattrass suture of catgut, without drainage, and the leg up to the groin is placed in a plaster of Paris splint for three weeks. Passive motion and massage are begun.

The advantages of this procedure are that, with no sacrifice of joint cartilage, a minimum of joint injury is produced at the time of operation, thereby greatly lessening the chances of limitation of motion, the formation of adhesions or future joint changes (osteoarthritis, etc.), and that the permanent blocking of any further tendency to displacement of the patella is effected by the actual elevation of the external condyle. The soft parts are not interfered with, and the only further suggestion in the case of extremely lax and stretched internal capsular ligaments is their plication with kangaroo tendon; but usually this is unnecessary, for if the external condyle is propped well forward it in itself fulfills all requirements.

THE LYING-IN OF GARGAMELLE.

By Douglass W. Montgomery, M.D.,
San Francisco, Cal.

Rabelais as a Realist.—Prof. Abel Lefranc of the Collège de France, one of the most thoughtful critics of Rabelais, says that the author of Pantagruel never invents anything in its totality; a memory, a fact, a precise circumstance always forms the foundation of his most fantastical conceptions, and frequently even of most of the details of which the foundation is composed. This law of Rabelais' intellect may, he says, be constantly verified.

The lying-in of Gargamelle forms a striking example of this habit of authorship, and in many ways it forms one of the most interesting descriptions of an obstetrical case ever published. It is really a village scene, a bit of folk life, precious because composed when historians considered it beneath them to regard the life of the people, and physicians did not occupy themselves with parturition.

Although in the sixteenth century physicians took little interest in obstetrics, and its literature was scanty, yet Rabelais probably read the section on this branch in Celsus, and may have talked over the details with his friend, Dr. Rondelet, who would likely know just the points required for the story.* This does not diminish the merit of Rabelais' achievement, but rather heightens it. A genius may gather gold from any quarter, but the finished coin always bears the author's stamp.

The Marriage of Grangousier to Gargamelle.—Grangousier was a jolly bachelor and a merry companion who had arrived at the age when men take

*The Doctor Rondibilis of Rabelais' story was really Dr. Rondelet, a friend, who practised medicine in Montpellier.—La Vie de Rabelais, par Paul Stapfer, 1906, p. 50.

their drinks neat, and when, furthermore, they often feel under the necessity of eating salty, highly seasoned dainties in order to accentuate their appetite for a glass. He had got together a goodly store of worldly possessions, of which Rabelais takes the trouble to give us an enumeration of those that lend themselves to sociability. While he was still a solid citizen he bethought him of a wife. Here the form of the author's sentence, "En son eage virile" together with the above-mentioned facts, would indicate that Grangousier would be about forty or forty-five, this being admittedly the age of the plenitude of force and virility in the male. Just at this time he undertook a daring adventure, quite characteristic of those virile men who are successful in life and yet defer the date of marriage. He married a young, pretty girl. In spite of disparity in years, however, there is nothing in the story of Grangousier and Gargamelle to indicate that they did not love one another dearly; in fact quite the reverse is the case. In due course Gargamelle became pregnant.

When a man, well along in years, who has acquired much more than a competency, suddenly finds himself in the expectancy of having an heir to his possessions, he commonly indulges in some mad caper, and the most usual form it takes is a feast with abundance of wine and unstinted hilarity. And certainly the feast that Rabelais there describes is without parallel. Possibly there never has been given a better description of the disconnected remarks and the inconsequentiality produced by alcohol.

The pretext for holding the feast was a large quantity of the tenderest most succulent tripe obtained from the slaughter of a great number of the fattest, sleekest cattle, pastured on the richest grass of the wonderfully fertile land of Touraine. The tripe was so tender and rich that Grangousier felt anxious lest it should spoil, and curiously enough this anxiety culminated at the term of Gargamelle's pregnancy.

Just before the confinement, Grangousier indulged in another temerity, quite in accord with his old bachelor ideas. He advised his wife to be sparing in her eating of the delicious tripe. This is a touch such as a medical man, turned author, would give. How often has a mature physician to advise irresponsible young girls as to their food! We all know how futile such admonitions are unless backed by a statement as to the detrimental effects of bad eating on their good looks. Gargamelle, however, did not abstain; on the contrary she proceeded to eat abundantly of that tripe. These pretty featured young girls have the self-indulgence, truculence, and lack of restraint of children, combined with the adult's feeling of immunity from corporal punishment. A lineal descendent of Gargamelle, a large, pulpy, good-natured woman, once sought my advice. In answer to a question regarding her diet, she said, "Everything that looks good I eat." It is well known also that pregnant women are often whimsical in their appetite, and will conceive a violent desire for some particular kind of food, and very especially so if forbidden.

Grangousier's motive in advising moderation was kindly in act and medically sound in principle. There is an old Latin proverb to the effect that, "The best things undergo the worst corruption." This holds good for the Church, the State, and for food. As regards food the reason for it is clear. The component parts of these good things, as of this fat tripe, are so fluid and soluble that they quickly come in contact with the taste corpuscles, and we are told that the savor of this particular dish of tripe was so delightful that you would lick your fingers after partaking of it. This very fluidity, solubility, and ease of dissociation, however, render such food readily fermentable, and therefore liable to cause intestinal intoxication. It was this very fluidity, ease of dissociation, and aptness to putridity that induced Grangousier to warn Gargamelle against eating it, especially when she was on the point of lying-in. Rabelais does not state that constipation, which is such a frequent accompaniment of gravidity, would add immeasurably to this risk of putrefaction, but he does state that the tripe caused a wonderful deal of gas in Gargamelle's bowels, and there is no doubt he connects it with the prolapse of the rectum that the fair patient suffered during her subsequent confinement. All these matters in their practical application were undoubtedly folk lore in Rabelais' native country.

The actual lying-in is distinguished by the absence of male attendance. The Queen was confined by midwives, and by mature experienced ones, and by a very considerable number of them, and the one who took the lead was a dirty old trot, who owed her preeminence to experience acquired outside the laws of morality. She was esteemed a great she-doctor. If a medical man had been suggested for such an occasion probably Rabelais would have been the first to raise his eyebrows in astonishment.

The husband, however, was present and the lightsome yet tender and thoughtful way in which he comforted his wife in her trouble is one of the truest, most touching scenes in literature. Her answers to him, scoldingly affectionate, are just as true both as to circumstance and to human nature.

After comforting his wife for a space, Grangousier hastened off to his companions to have another glass and to enjoy himself, for all the neighbors were gloriously drunk at the feast on the before mentioned succulent tripe.

Before leaving his wife to join these merry companions Grangousier assured her he would be on the alert, and that if she needed him she had only to put her hands to her month and shout and he would be right on the spot.

Husbands have acted in this way since the beginning of the world. The distress and the waiting are a weariness to them, and they hurry to their work or to the club, and yet they wish to be within easy call so that they may arrive plump at the joyful moment.

And imagine Gargamelle, while in a labor pain, shouting! One suspects that this is one of Rabelais' jokes. She would hold her breath and groan.

My offices are across the hall from an extracting specialist; one who pulls teeth to gain enough to entertain the needs of the flesh, until such time as he shall finally give up the ghost. From time to time there are heard varied tones of expletive eloquence wrung from his patients through torment of the fifth nerve. These free, wild, high pitched notes are quite different from the low groans with retention of breath that emanate from a lying-in hospital.

The course of the labor was obstructed, and instead of the infant being born *per vias naturales*, it took a course through the cotyledons of the uterus, and from there into the inferior vena cava, the superior vena cava, the jugular vein, and out through the ear. This looks in its entirety as a joke, but

like many a thing in Rabelais' works it may be something more. It may readily be that the ears were supposed to have a direct connection with the veins. A striking example of this is in the poisoning of Hamlet's father. The ghost tells Hamlet that while asleep in his garden his brother stole in upon him and poured poison into his ear. This poison immediately attained the blood, which it curdled like eager droppings into milk. In Rabelais' time and down to Shakespeare's day it was commonly supposed that the veins alone conveyed the blood, and that the arteries carried air. The large venous sinuses in the temporal bone and in its neighborhood may have lent themselves to the idea that there was a direct connection between them and the ear and so on to the outer air, and both the birth of Gargantua and the poisoning of Hamlet's father may be expressions arising from this common idea.

As regards the other end of the venous channel through which the fetus took its way, there is good reason for believing that Rabelais thought the veins of the uterus ended in real cotyledons or cuplike suckers, and that these being sympathetically relaxed, owing to a strong contraction of the tissues of the vaginal and anal orifices, brought about by the topical application of a most powerful astringent, opened the way for the fetus to enter the inferior vena cava. The very word itself, cotyla, a half pint measure, would appeal to a literary man and a Greek scholar like Rabelais as good evidence of the above view. Rabelais was not a scientist, he was a most accomplished and learned story teller. Furthermore, Rabelais in this instance, as in so many others, was probably quite in accord with contemporary opinion. In 1632 T. Johnson wrote, in translating Parey's (Paré's?) Chirurgie: "The cotyledons (of the uterus) . . . . are nothing else than the orifices and mouths of the veins ending in that place."[1] Here it will be noticed that Johnson speaks of the cotyledons of the uterus, as does Rabelais, as orifices in the uterine wall. In the Oxford Dictionary the cotyledons are defined as the lobes or divisions of the placenta, or the corresponding areas of the internal surface of the uterus to which they are attached, making the term apply both to the uterus and to the placenta, an evident partial harking back to the old views. I think, however, that almost every medical man in this country, if he uses the term at all, restricts its employment to the lobes or divisions of the placenta alone, and if he reflects on the literal meaning of the term, considers that the placenta may be regarded as having a fancied resemblance to a fruit-bearing pod, of which the cord is the stem and the cotyledons the compartments. This represents a totally different state of affairs from that imagined by Rabelais. I have no doubt, therefore, that Rabelais, in his burlesquing way, imagined the fetus entering a real cuplike opening in the uterine wall in commencing its celebrated venous excursion. I, of course, do not mean to indicate that Rabelais considered that these openings, communicating with the venous system, were large. That they popularly were supposed to exist would, however, furnish the necessary basis for a joking allusion to them.

A lack of the knowledge of the circulation of the blood lead to many a queer idea in medieval medicine. For instance it was at one time thought that the beautiful blue, violet, and azure colors of the venules, in the foot in those who suffer from varicose veins, were due to the bile escaping from the liver by the hepatic vein, and settling down through the inferior vena cava, iliac, and femoral veins to the lower extremities. The modern habit of visualizing the circulation, that is now involuntary with every well trained medical man, was then impossible.

Although Rabelais was not an accoucheur, and probably never attended a woman in that capacity, yet there is no doubt from this description that he took a wonderfully human interest in the whole procedure.

We have still another of his writings showing how interested he was in pregnancy, and how it appealed to his imagination. This is his letter to Erasmus, written in the fall of 1532, and contemporaneously with the appearance of the second book of his works. The following is a translation:

"My father, have I said? I would say my mother, if by your indulgence you may permit me. For what we see daily occur to women who nourish the fruit of their womb without even having seen it, and protect it against the rudeness of the air, that you have done also, you, who knowing neither my face nor my name, have raised and nourished me at the chaste breasts of your divine knowledge. Yes, all that I am, all that I am worth, I owe to you, and if I do not proclaim it, I am the most ungrateful of men either now or in the time to come. Greetings and double greetings dear father, father and honor to your country, tutelary genius of letters, and invincible champion of truth."[2]

Furthermore, in the renaissance, writers seem to have been quite intent on pregnancy and labor as a symbol. The reason for this will be touched upon later. Servetus, for instance, compares the whole Law of the Old Testament to a pregnant woman, who is about to give birth to a Divine Son.[4]

After having created the character of Gargamelle, and after having conducted her through a most eventful childbirth, Rabelais says that he later learned she died of joy after a feast given in celebration of the return of Gargantua, her son, from the wars. He denies all personal knowledge of this, however, and says that he is interested neither in her nor in any other woman.[5] Stapfer cites this as an example of Rabelais' contempt for women.[1]

The touch is truly Rabelaisian in yet another sense. He constructed the character of Gargamelle as a motherly wifely woman, and such a piece of work is not done offhand. It must have cost him many a painstaking moment; and yet neither Nature herself nor Shakespeare could have thrown away a beautiful piece of work more carelessly. There is yet another explanation of his contemptuous dismissal of the subject of Gargamelle. It may be truly said that whenever one wishes to know the train of thought in the Middle Ages, first consult Rabelais. This apparent contempt for women may simply be a reflection of one of the prevailing doctrines of the times, that the soul of the progeny was from the father, and that the body, and the body alone, was entirely elaborated by the mother.*

Had Rabelais, in writing the lying-in of Gargamelle, any further object than to do a good piece of realistic work in describing such an occurrence in the rural part of France, in which he was born? It is the custom to attribute a hidden meaning to everything that the great Tourangian has written, but we must take his own warning, not to put on those magic spectacles by which letters that do not exist

*Servetus speaks of this theory. See Michael Servetus, by C. T. Odhner.[3] In the Middle Ages theories were often accepted as facts.

are read. Nevertheless a little speculation may be indulged in, provided one announces before hand that it is speculation.

Long before the period this story was written the story of the Nativity was lovingly idealized into the most beautiful forms, and those idealizations reached their height in the Renaissance. Every great spiritual exaltation finds its expression in art, and Raphael was the towering genius of a vast movement engaged in depicting the wonder and mystery attaching to impregnation, parturition, maternal love and the blessing of children. Raphael's representations of motherhood have never been surpassed. The enthusiasm for this form of art was all-pervading and irresistible. Cardinals, with immense incomes, lived in the most simple way in order to have money to devote to it. The cult of the virgin mother reached dimensions, and an exquisite refinement, of which we, living in an age in which mechanical, chemical, and social efficiency are the objects of interest, can form only a dim conception. The best things, however, as has before been mentioned, undergo the worst corruption, and these enthusiasts were willing to go to any length in order to satisfy their love of the beautiful. The madness of mysticism culminated in the Thirty Years War, just as the mania of mechanical, chemical, and social efficiency culminated in the great European War of 1914. The one group of enthusiasts wished to impose their mysticism on Europe in its entirety, the other party wished to organize Europe in its entirety according to their social ideas.

There is no doubt that the lying-in of Gargamelle forms a wonderfully well elaborated antithesis to the mystic cult of Christianity. Grangousier was a great healthy man, a good provider, who loved his family and his neighbors in a perfectly material way, and with whom ministry to the flesh was no toil; it was a joy. In this Commonwealth of California he would be elected to any political office he might wish to contest. His wife was pretty, and enjoyed the good things of this world, even as he did, thoroughly. The baby, of which we have not yet spoken, was the perfect product of these two. It was a great, healthy baby, that grew into a great rollicking boy. The description of the baby and the boy are masterpieces. There is no doubt that the Nativity of Gargantua is as absolutely devoid of mysticism as can be imagined.

As a story also the lying-in of Gargamelle is perfect. It begins by showing the station and way of life of the hero and heroine. Then comes the catastrophe, due to the peculiar mode of birth of the infant, on which follows a happy ending.

The highest form of humor must necessarily have a most serious basis, and if we take into consideration the carefully realistic way this story was worked up, its perfect form, and its striking materialism, and then imagine a people imbued with mysticism until many of them were heartily tired of it, we can get a faint inkling of the roars of laughter that greeted this new departure in literature.

The world moves, and it moves in a circle, and we shall see many things before we die.

SEVEN CLUES TO BALDPATE.

By WILLIAM P. CUNNINGHAM, A.M., M.D.,

NEW YORK.

ASSISTANT DERMATOLOGIST, HARLEM HOSPITAL; CLINICAL ASSISTANT, NEW YORK SKIN AND CANCER HOSPITAL.

Woman's crowning glory is her hair; one of her greatest griefs, to see it go. So keenly does she feel its slow deletion that she will save and wind and hoard each falling strand to weave, in that much dreaded day when baldness yawns, the cunning false presentment of a crown. So conscious is she of the need of this that she will even buy the hair of other heads and heap it in profusion on her own. To her the preservation of her hair is something vital and innate. Her consort, while bedecked by nature with a less luxuriant growth, is nevertheless concerned about its permanence, especially as the years forbode a tonsure. He notes with marked anxiety the thinning at the top, and ingeniously manipulates the more resistant filaments to hide the shining scalp. This artifice is usually futile. No eye is deceived by it except his own. This aversion to yielding to the ravages of time is not always prompted by discreditable vanity. Bald heads and gray hair are regarded as the evidences of the degenerative changes coming with advancing age and associated with a "slowing up" of bodily activity. Viewed in this light they are a detriment to the seeker for employment. Oftentimes their significance is utterly misconstrued. The baldness or the grayness may not be due to age, but disease or idiosyncrasy. Again they may be compatible in very many cases with unimpaired vitality, sobered and enhanced by the wisdom of experience. But in general terms it is admitted that the possession of a bald or whitening head is in most of the paths of industry a very undesirable asset. Thus the preservation of the hair from premature decadence is a matter of very serious moment and well worth our earnest consideration. The accomplishment of this very meritorious object depends on several factors, which we will develop seriatim.

Let us admit at the beginning that the distinctive effects of age cannot be stayed. We can no more forestall the withered wisps of the lean and slippered pantaloon than we can his shrunken shank and childish treble and doddering imbecility. But senility accelerated by disease, by vice, by poverty and hardship, may, if these conditions can be met and changed, be markedly retarded in its march. Worry will whiten a man at thirty, will bend his back at forty, and make a hopeless wreck of him at fifty. Dissipation, disease, and continual exposure to exhausting conditions with insufficient nutriment will accomplish the same result. There are means, economic, moral, and medicinal, which may obviate these precipitants. Here and there we may be able to lift the burden of the worrier, to reduce the rake to reason, to upbuild the victim of privation, to stiffen a tottering constitution, but in the present construction of society it is conceded that such instances stand forth in significant isolation. Idiosyncrasies there are, inherited and ineradicable, which blanch or thin the hair of youthful heads. How often have we seen the vivid eye and ruddy cheek of youth in startling contrast with the thin retreating locks of hoary age! Obviously we can offer no remedy for this. Realizing that the nurture of the hair is dependent on the vascularization and innervation of the follicle, it is indubitable that in many conditions of lowered vitality of a temporary

and remediable nature its growth will sustain a perceptible setback. Note the defluvium capillorum of acute infectious fevers; note the diminution due to anemia. Tonics, alimentary, medicinal, and climatic, will work a marked improvement here. But all the general measures looking to the health of the individual will be utterly disappointing if the local causes of the failing follicles are overlooked. These are alopecia areata, seborrhea (sicca and oleosa), folliculitis decalvans, favus, lupus, erythematosus, morphea, and dermatitis exfoliativa. Alopecia areata may deplete the scalp in circles large and small, in great irregular areas, or *in toto*. Its appearance is sudden as a rule and preceded by no admonitory symptoms. The hair just falls away like the bristles of a brush that gets the heat. To-night a man retires in happy unconsciousness of impending trouble, and in the morning his massy locks are shot with denudations. Alopecia areata totalis sweeps every vestige of a hair from off the scalp, and even off the face and body. This extreme defection is unusual and hopeless. The partial losses are many times restored by the inexplicable suspension of the inexplicable cause. This occurs in response to certain vaunted methods of treatment in some undeniable instances. That it also occurs spontaneously in the absence of any treatment whatsoever is a matter of common information. As we have nothing but surmise regarding the etiology, as to whether it is parasitic, reflex from the eye, intestinal tract, or some other undetermined source, the frequent spontaneity of the cure lends a merited suspicion to our successful (?) therapeutics. Ninety-five per cent carbolic acid is credited with stimulating the follicles in a most astonishing way; the correction of errors of refraction instantly releases the nervous inhibition that has paralyzed their function; the removal of intestinal putrefaction by a rational diet and appropriate medication has several times appealed to me as etiologically significant; yet all of these measures lose in importance when it is recalled that many cases fail in spite of them, and many others are cured without any regard to them. The coincidental removal of the operating cause is the only logical deduction from these observations. It is comforting to realize that most cases of moderate severity have a natural tendency to recovery.

Pityriasis rubra and its less destructive counterfeit, dermatitis exfoliativa, both attack the scalp and may leave it a grotesque waste of struggling tufts. If the hair returns it is apt to be thin and white. Fortunately, these diseases are rather rare. Lupus erythematosus is widely known and readily recognized as the "butterfly" disease when it appears in its classical situation upon the nose and adjacent cheeks. The sharply defined redness, the scanty and adherent scales, the gaping follicles beneath, the spots of atrophy marking the involution of the process, combine to form a clinical picture of an unequivocal character. But it is a disease of a roving disposition and does not confine itself to the classical location. It invades the ears, inside and out, occasionally it travels very far afield, and attacks the fingers. Frequently it appears upon the scalp. The lesions may be small or extensive. There may be a single lesion no bigger than a dime, or several of them; there may be an involvement of the entire scalp above the level of the ears. All gradations between these extremes have been noted. The termination of the process being by atrophic scarring, the hair follicles are wiped out and the baldness is permanent. The smaller foci naturally leave but little surface to conceal, and the hair may be drawn across them. The extensive foci are so disfiguring that the embarrassed victim is forced from consideration of sheer self-respect to resort to a wig. Very little difficulty is experienced in making the diagnosis if the characteristic features of the disease are kept in mind. Error will proceed only from precipitancy. Diffuse symmetrical scleroderma, or circumscribed scleroderma, otherwise known as morphea, may be found upon the head where the hair follicles will be obliterated in the infiltration or atrophy of the skin. The vitreous density of the affected area, with its ivory white or faintly yellow tinge encircled by a narrow lilac band, is so distinctive of this mysterious malady that there is little likelihood of mistaking it. It is hardly necessary to observe that, in order to uncover all these characters of the sclerodermatous patch, we may be forced to shave the hair for a narrow margin around it. The origin of this disease is absolutely unknown, and its treatment useless. Many cases recover spontaneously, as we glibly phrase it, that is, by the operation of forces, of the nature and source of which we have not the least idea. The destruction accomplished by the condensation of the tissues is apt to be permanent, and the hair follicles may not functionate again.

Folliculitis decalvans is a suppurative inflammation of the follicles of the scalp, resulting in baldness. It is a sort of barber's itch of the scalp. There is little doubt that the cause is parasitic, but the organism has not been defined. Each little pustule is pierced by a hair, which promptly falls, never to return. The area traversed varies. It has included the entire top of the head. Freaky exemption of individual follicles has been noted right in the track of its massed advance. An account is given by a noted dermatologist, whose veracity is above suspicion, of a case of folliculitis decalvans where the calvarium was entirely denuded of hair save for a single sprig in the midst of the desert, to which was desperately clinging—a solitary nit! Treatment is disappointing. That is euphony for useless.

Favus, as is generally understood, lays waste the ground that it has attacked. This is such a rebellious disease to treat that it may be conceded that it is practically incurable save by the lapse of time and the slow devitalization of the parasite. It is recognized by its yellow crusts made up of little cups, its mousy odor, and its always being an importation. The crusts look like sulphur paste. The cups are little petal-like formations of the activating fungus. On detachment a little reddish depression is disclosed, which eventually becomes one of the glistening pinkish scars that tell the tale in after years. As in ringworm, the invasion is of the hair follicles, and the fungus forms around the protruding hair like a tiny collarette. The invasion of the follicles is apparently somewhat capricious, as the resulting alopecia is apt to be of a very irregular and zigzag character. We have said that favus is practically incurable. That statement holds. Persistence in the antiseptic measures recommended should eventually bring it under control, just as in ringworm. The *x*-ray offers the same relief to both. But "practically" the treatment yields only disappointment, because the patients are of a class who will not persist long enough in any line of effort to effect a result.

It is only when tinea tonsurans forms a kerion

that incurable baldness results, so we will defer its consideration for a moment or two. All the causes of baldness hitherto recited, except alopecia areata, are irremediable, meaning that when the disease has struck, the affected area is permanently denuded. We have seen that alopecia areata may yield completely and leave no trace, "more," as the pithy Irish phrase it, "by good luck than good management." Fortunately the irremediable is also rare. The commonest cause of alopecia is quite amenable to proper management. If prophylaxis of the scalp were as regularly practised as prophylaxis of the teeth in the adolescent, wilted hair and premature defluvium would be the rarest of complaints. But the sober truth is that with few exceptions attention to the scalp is confined to periodic or episodic washings, with a tendency to aggravate the incipient disease. The practice of brushing the scalp briskly with a good stiff implement will, by removing the deciduous epithelium and stimulating the blood and nerve supply, prevent the development of the rebellious condition known as seborrhea sicca. This is one of the phases of seborrheic dermatitis, which is the disease responsible for most of the overt baldness of men and covert baldness of women. It is a disease of the sebaceous glands, just as acne is, but instead of the orifice being occluded and forming a papule or pustule, the gland exudes a freer secretion, which may be distinctly greasy, as it should be, or altered by the inflammatory element to such a consistency that it dries into flakes, just like the paste around the neck of a tube of mucilage. The orifices of the sebaceous glands open into the hair follicles, and that is why the hair is lost. It is choked by the inflammatory exudate. Both in seborrhea oleosa and seborrhea sicca, this loss is observed, because they are variants of the one pathological process. The dried secretion, if rubbed between the fingers, will, after a certain amount of friction, impart an unctuous feel, demonstrating the fatty basis of its composition. When the inflammatory element predominates, a condition resembling eczema is produced, lacking, however, the vesiculation always attending the latter. The term "seborrhoic eczema" is therefore a misnomer. Both Sabouraud and Unna attribute the disease to an organism. This has not been demonstrated to the satisfaction of every one. It has much to commend it, however, such as follicular invasion, circinate outline, and auto- and probably hetero-inoculability.

The diagnosis of seborrheic dermatitis of the scalp is usually a matter of little difficulty. It is the commonest disease of that region. There is either an abnormally greasy head or one covered with powdery scales. There is sooner or later noticeable hair loss. It may be confounded with psoriasis when the latter is limited to the scalp. Typical patches on the body would clear up the case at once. For one thing, psoriasis *does not cause the hair to fall.* Again, psoriasis creeps beyond the hair line down on the forehead. Seborrheic dermatitis is less likely to do this, although it is prone to appear on the forehead as a separate manifestation. The psoriasis scales are not greasy; they are pearly and remain dry under friction.

The prognosis of established seborrhoic dermatitis is problematical. It is a very hard thing to cure. Note the word "cure." Temporary alleviation may be effected, but relapse is the rule. Several factors are responsible for this. One is the unassailability of the process deep in the sebaceous gland. Another is the presence of the hair, rendering effective applications difficult. Another is the well-known disinclination of patients to pursue a course of treatment that is tedious and for a long time apparently unavailing. Given a perfect combination of favorable circumstances, however, and progress will still be exasperatingly slow and uncertain. The means to be employed are resorcin, sulphur, ammoniated mercury, and bichloride of mercury. Ammoniated mercury is applied in ointments; sulphur in the same way, or in a lotion, as the hyposulphite; resorcin and bichloride alone or combined are used in liquid form. Where the scalp is excessively greasy, alcohol may be added with advantage to the lotion. Some authorities favor the use of salicylic acid in conjunction with sulphur. Water should be employed as sparingly as possible. Even for the removal of accumulated débris it is of doubtful utility, because of its propensity to aggravate the dermatitis. It is better to combine it with alchool for the purpose of a shampoo when this is deemed indispensable. But it will be found that the salves and lotions recommended for the disease will keep the scalp reasonably clean. It is self-evident that if the hair is kept short, applications can be more effectively made. This is out of the question in women. It is perfectly practicable in men. It should be borne in mind that the object of attack is the *skin* of the head, not the *hair*. So it is not necessary to besmear the *hair* with any greasy or sticky remedies, which disgust and discourage the patient.

The scalp is the field of many other disorders, some of them peculiar thereunto, and others more or less widely distributed over the integument. Psoriasis has already been referred to. The scalp is one of the commonest sites of this remarkable neurosis. Its resemblance to seborrheic dermatitis is striking, as we have observed. The distinctions were drawn in discussing the latter. The neurotic hypothesis, usually decried, has received unlooked for and grudging support from the advocates of an autoserum in the treatment of this extremely rebellious and persistently relapsing dermatosis. They claim, and I think fairly, some convincing results. They concede their inability to account for them. There is some cloudy discourse about aroused antagonism and altered metabolism, but of logical explanation there is none. But if we postulate psoriasis as a trophoneurosis, or rather as a *dystrophoneurosis*, we get a rational hold of the situation. The reinjecting of the patient's defibrinated serum can not conceivably add anything nutritional to the blood or cells, as it simply replaces part of what had been extracted. But we are sustained in our belief that the process of withdrawal and replacement, the alternations in the patient's blood pressure, and the psychical effect inseparable from the whole proceeding, produce such a reaction upon the nervous mechanism as to inhibit the faulty impulses or arouse eutrophic ones. I have published a record of certain cases where exhilarating intelligence, a change of scene, an ocean voyage, a vacation in the hills, achieved a complete disappearance of the eruption. The fact that chrysarobin in weak proportions has to be used in conjunction with the autoserum in order to clear the skin, is added evidence of nervous intermediation, because if the lesions were autotoxic or metabolic no external sitmulus would be needed. Failing an autoserum, ammoniated mercury is the best application to psoriasis of the scalp.

Tinea tonsurans causes areas of temporary baldness in children. The outlines are circular, unless

they coalesce, when they are apt to become irregular. Sometimes the scalp is almost entirely covered with small scaly denuded foci that would suggest the comparison of a stubble field of a very stony character. A case of this sort is apt to be mistaken for a seborrheic dermatitis, unless it is recalled that ringworm is confined to children, that it deletes in patches instead of thinning the hair, and that the scaly surface will show some broken shafts. Of course, the microscope can be called upon in case of indecision. Unless a kerion forms, the growth will be re-established on that happy but usually long-deferred occasion when the parasite succumbs. A kerion is a suppurating ringworm. The patch swells up and oozes pus from the mouths of many follicles. This complication quickly jugulates the disease, but it also destroys the hair, for the site of kerion is forever bald. The treatment of ringworm of the scalp is a veritable labor of Sisyphus. The most loyal adherence to the most intelligent management will be rewarded with continual disappointment. Patients grumble and pass on, only to experience the same dissatisfaction in other hands. The remedies comprise practically the whole range of antiseptics. The difficulty does not lie in a dearth of effective remedies, as witness the ready cure of ringworm of the body; it lies in the almost impossible task of forcing the strait of the follicle, with its stump of a broken hair. Mechanical epilation is not successful because the hairs break off so easily. Whatever remedy is selected, it should be rubbed in vigorously with a toothbrush or a stencil brush cut short. Iodine in glycerin is as reliable as any. Red oxide of mercury ointment alone or in combination with sulphur with a zinc oxide base has much to recommend it. A depilatory of barium sulphide is advised by Stelwagon as the preliminary means of attack, as it rids the patch of stumps and opens the follicles to the assaults of the selected parasiticide. Bulkley favors the use of a combination of mercury and iodine ointment, equal parts, making nascent iodide of mercury. All applications should be rubbed in *until they hurt*. The finger should never be employed for this purpose, as ringworm attacks the nails and sets up a most obstinate disfiguring and disabling condition, styled onychomycosis. If the patches are clearly outlined the hair should be shaved for an inch around it, just as woodmen cut a circle around a burning copse to prevent the advance of the flames. There is no question of the efficacy of the *x*-ray in the treatment of tinea tonsurans. Neither is there any question of its inducing permanent baldness if it is unskillfully handled. Furthermore, it is not always available for people of limited means. Puberty definitely disposes of any lingering tinea tonsurans defying medication. How or why it does so we do not understand.

At first glance it would appear to be a clear waste of valuable time to bring to the physician's attention such a widely diffused, readily suspected and easily recognized condition as pediculosis capitis. Every mother can diagnose it without the doctor's aid. Just so. But as a matter of fact pediculosis capitis turns up under circumstances that befog the eye of judgment, and obviate detection. In a dirty, frowsy, unkempt child, itching of the scalp would arouse our prompt suspicion. In a careless, slovenly, "clotty" woman this would make us equally alert. But now suppose a cleanly, tidy, well-groomed child presents, the product of incomparably better conditions, is it likely that we shall give this loathsome, filth-engendered thing a moment's consideration? Is it likely that a routine inspection of the head will reveal the truth where soap and water have been used in such profusion? Is it not a fact that the diagnosis will range over seborrhea, eczema, urticaria, and that miserable evasion of all responsibility—pruritus? The evidences may be difficult to locate—a few resistant nits clinging to some deeply buried strands, but nothing in the social status of the patient should preclude investigation. Witness the invasion by these parasitic sansculottes of a fashionable boarding school for young ladies in the experience of Dr. Bulkley. The superiors and pupils were horrified and outraged by the preposterous diagnosis. The thing was unthinkable! Its occurrence impossible! Incontrovertible evidence in the shape of nits demonstrated by the microscope finally brought home to them the humiliating conviction that they were as susceptible as their poorer sisters to this nauseating infliction under a proper conjunction of circumstances! It is rarer in men owing to the less inviting recesses for the seclusion of the parasite. But do not exclude it on that account. Be wary always. An eczema at the nape of the neck, enlargement of the postcervical glands without other evidences of "struma," a pustular dermatitis of the scalp, no matter how limited in extent, should suggest at once the possibility of pediculosis, and it should not be dismissed until it is absolutely, definitely and decisively disposed of. The treatment is within the grasp of every physician. To complete the record it may not be amiss, however, to recall it. Kerosene at night, with a towel wrapped about the head. In the morning a combing with a fine-toothed comb that has lain in vinegar over night. After this the application of ammoniated mercury ointment in full strength. If a single nit eludes elimination the regeneration of the obscene breed will quickly supervene. Pediculosis excluded, pustular lesions of the scalp come under the catagory of impetigo contagiosa, impetigo of Bockhart, impetiginous eczema, post-varicellam infections, acne varioliformis, and syphilis.

Impetigo contagiosa displays the same characteristics in the scalp as elsewhere. It is seldom limited to that region. It is superficial, honey-colored and gives the impression of being pasted on the skin. These features may be difficult to discern in the hairy scalp, but one spot elsewhere will bring the light. The impetigo of Bockhart consists of follicular abscesses; it is caused by the staphylococcus instead of the streptococcus which causes the ordinary form of impetigo. Scarring will follow, owing to the location of the suppurative process about the hair. If agminated, it bears some resemblance to kerion. The remedy for both of these varieties of impetigo is ammoniated mercury.

The infection of varicella lesions will result in ecthymatous sloughing and crusting. In the cachectic this is apt to be grave. On the scalp such manifestations take a more rebellious form because of the luxuriance of all infections in that fertile locality. The local treatment is identical with that for impetigo, with additional internal remedies for the depressed vitality which nearly always accompanies such untoward developments. A peculiar rupial crusting is sometimes seen in varicellous lesions, which would be decidedly misleading if it were not for the accompaniment of typical pitting elsewhere.

Lupus vulgaris, a true tuberculosis of the skin, never affects the scalp. We have seen that lupus

erythematosus does. The latter is a tuberculide. A tuberculide is a disease produced by the toxins of the bacilli, not directly by the bacilli themselves. It is not innoculable; its genealogy is inferential. It is presumed to have its origin in the tuberculous diathesis, but it is so frequently found in robust individuals that its title is a bit involved. However, certain skin disorders are denominated tuberculides, and among them one yclept acne varioliformis. This affects well-defined areas on the face, and also runs up into the hair. Small pustular lesions form, with evolution into a flat papule with a depressed center, terminating in a small depressed scar. It is mistakable for nothing but a punctate syphiloderm, which would display a tendency to grouping and unilateralism not found in the tuberculide. The treatment is that for ordinary acne, thus casting a heavier shadow on its tuberculous pretensions.

At the nape of the neck occurs a neoplasm with a portentous title, following a pustular folliculitis. It is called Dermatitis papillaris capillitii; it is a keloid, a little more sanely denominated by the French acne keloid. As the follicular infection is multiple, so is this mysterious consequence. The origin of keliod is absolutely unknown. The remedy is the *x*-ray.

Impetiginous eczema is frequent on the scalp. It is an infelicitous title, as it would seem to indicate a peculiar and distinctive variety of eczema, whereas the actual fact is that it is a pus infection on an eczematous base. The ordinary features of eczema —infiltration, oozing, and itching, precede the pustulation. Scratching by dirty finger nails, rubbing with dirty hands, covering with dirty hoods and shawls, and access to the pestilential fly, are the occasions of this disgusting complication. Before any impression can be made upon the underlying condition the suppuration must be overcome. Weak ointments of ammoniated mercury, ointments of ichthyol, and oily preparations of salicylic acid are available for this purpose. I should like to digress for a moment to call attention to a peculiar property of one of the remedies frequently mentioned in this paper as a parasiticide. Ammoniated mercury is highly efficient in that regard. It is indicated in the attack on parasitic and purulent outbreaks. But curiously enough, if suppuration has not occurred, as in eczema marginatum or tinea circinata, or seborrhea, it is very likely to excite it. Yet against actually existing suppuration it is a most reliable agent. Always be on the lookout for this, or there may be embarrassing explanations to make. It has been impressed already that no impetiginous eczema of the scalp should be considered thoroughly overhauled without an exhaustive hunt for pediculosis and tinea tonsurans. *A priori,* if impetiginous eczema is found on the scalp, eczema vulgaris must occur there. This corresponds with experience. It has the make-up of eczema everywhere. It is infiltrated, vesicular, scaly, ill-defined in outline, and itchy. From seborrhea it is distinguished by its vesiculation, its thinner scales, and the stability of the hair. From psoriasis it is distinguished by its vesiculation, its thinner scales, and its insistent itching.

It is to be supposed that a disease so unstinted and impartial in its attentions to the different tissues and organs of the economy as pantomorphic lues, would not fail to make its impression on the scalp. This supposition is supported by the facts. Lues visits the head, inside and out, with a great deal of assiduity. It is a matter of general knowledge that where there is a succession of external explosions there will be comparative freedom from the graver internal manifestations. The repulsive gumma on the scalp is in this point of view a positive blessing as assurance against a similar growth within the cranium. This lesion may be of almost any size and almost any shape. It may be round, oval, crescentic, fluted, or any bizarre formation of broken interlacing circles. It may make a hole no bigger than a pencil-end, or it may involve an area many inches across. It may be confined to the skin and subcutaneous tissue, or it may delve into the bone. Besides its suggestive outline, it will display the characteristic perpendicular walls, meager inflammatory zone, and malodorous mephitic secretion. Lues, prolific of expedients, may attack under another guise, namely, that of the ulcerating tubercular syphiloderm. Here the term tubercular has no reference to the etiology, but only to the form of the lesion, a tubercle being an overgrown, plethoric papule. An outbreak of this sort is in the form of a group of these tubercles, three, four, or a dozen, always tending to a curvilinear outline, and each of them surmounted by a crust hiding a superficial excavation. If few, they may form the segment of a circle; if many, a complete one; if very numerous, they may take on the sinuous outline of a snapping whiplash. These manifestations are one-sided. A Liliputian representative of this large and varied family is found in the little papules with the minute central depressions which so closely resemble acne varioliformis, and from which they are distinguished by their unilateral grouping. In its earlier stages lues confines its depredations to the hair, thinning it evenly, removing it entirely, or munching out in tufts that leave a moth-eaten appearance. This last phenomenon is very significant. If you observe it and can get no confirmation of your suspicion from a self-deceived or mendacious patient, make a Wassermann test. It is unnecessary to speak of treatment in this day of intense concentration on that very subject. Luckily the medication, old and new, is potent to remove these symptoms. The ulcerating lesions leave scars. Epithelioma is seen upon the scalp, but not often; chancre also. A wart or scurfy spot may be the occasion of the one; the attentions of an infected barber the occasion of the other. Verruca vulgaris, molluscum contagiosum, cornu cutaneum, cysts, lipomata, fibromata, neurofibromata, angiomata, and keloid, are encountered often enough to keep us alive to the possibility. Leucoderma will reveal itself on the scalp in white patches of hair. The multiple benign sarcoid of Boeck is apt to be profuse upon the head. True sarcoma cutis may develop like epithelioma from a wart or mole. The small gritty papules of Darier's disease, with their horny plugs, are detected amid the hair. Ichthyosis, being a dry, harsh, scaling condition of the general surface, would naturally find expression in the scalp. The hair is dusty and lusterless, suggesting sage brush. Mycosis fungoides in the involvement of the general surface does not omit the scalp. The tumors destroy the hair.

Herpes zoster will be discovered on the top of the head, and a mysterious neuralgia in that location will be explained by the outcropping of the vesicles.

Epidermolysis bullosa, that extremely curious manifestation of highly sensitized sympathetic impulses, wherein the reaction to usually inappreciable friction is as violent as that ordinarily caused by steam, is as liable to raise its blisters on the scalp

as anywhere. All that is needed is the pressure of a hat band, the passing of a comb, the scratching of an itching spot. These evidences will be more prominent on other parts as being more liable to the insignificant violence that produces them.

Angioneurotic edema will raise enormous swellings in the scalp in accordance with its erratic visitation of the cutaneous surface. Dermatitis medicamontosa from bromides and iodides, and dermatitis venenata from the use of dyes and contact with such irritants as rhus toxicodendron are very much more distressing when the scalp is attacked. We know what a pretty mess is made by erysipelas when it gets into the same locality.

There are a few curious conditions which have a purely academic interest but which must be included to complete the record.

Fragilitas crinium reveals a feeble filamentary constitution, just as does fragilitas unguium. Monilethrix or beaded hair is characterized by fusiform enlargements, alternating with constrictions of the shaft. Trichorrhexis nodosa, consists of nodes scattered along the hair with a marked tendency to split at those points.

It will be admitted, I think, that the scalp is a region of considerable importance, not only to the dermatologist, but to the general clinician. There is a good deal to be learned from a study of it. Its management has much to do with the self-esteem and even the prosperity of many individuals. It would be decidedly to our advantage to devote ourselves to a systematic and thorough investigation of its pathology, to forestall, where that is possible, embarrassing disfigurements, and by correct prognosis to guard our reputations against venomous detraction.

THE THERMO-COUPLE THERMOMETER.

AN INSTRUMENT FOR THE EXACT MEASUREMENT OF TEMPERATURE IN LIVING TISSUES FOR USE IN COAGULATION SURGICAL PROCEDURES.

By ARTHUR FENWICK HOLDING, M.D.,

NEW YORK

DEPARTMENT OF APPLIED MEDICAL ELECTRICITY, CORNELL CANCER RESEARCH LABORATORY, GENERAL MEMORIAL HOSPITAL.

It has been shown by Haaland,[1] Clowes,[2] Lambert,[3] and Widal,[4] that cancer and sarcoma cells are killed by a temperature of 50°-55° C. (122°-131° F.) maintained for twenty minutes, whereas normal cells will not be killed until a temperature of 55°-60°C. (131°-140°F.) has been reached. These observations have been confirmed by the operative experiences of Doyen[5] and Percy.[6]

Taking advantage of this fact in the treatment of malignant tumors, Percy has devised his "cold cautery iron"; Doyen has used what he calls "electro-coagulation"; Nagelschmidt calls his method "diathermy"; Clark calls his method "desiccation"; Beer calls his "fulguration," etc. Many different surgeons working independently of one another in different parts of the world have reported new methods of treating malignant tumors by the coagulation of tissues without carbonization.

While these coagulation methods are probably the most important recent improvements in the surgery of malignant tumors, the weak point in the technique of the coagulation operations has been that one cannot apply the principles of selective heat temperatures. To overcome this difficulty and secure the benefits of selective heat treatment, I have employed a well known principle of heat measurement, so successfully used by physiologists in calorimetry and by metallurgists in the heat treatment of metals: namely the thermo-couple.

A thermo-couple is a fused junction between a constantin element and a copper element (Fig. 1). When the temperature of such a junction is heated or cooled, it generates a weak galvanic current which can be accurately shown on a calibrated reflecting galvanometer scale so as to register the temperature in the thermo-couple. The thermo-couple thermometer has the following parts: (1) A thermo-couple consisting of a wire of copper and a wire of constantin with their ends fused together. (2) A standard galvanic cell. (3) Two ordinary dry batteries in series with a standard set of resistances. (4) A reflecting galvanometer with its bar of reflected light falling on a special metric scale. (5) Switch boxes.

The standard cells and resistances are connected in series with the galvanometer to one side of the switch box; the dry batteries with the resistances are connected in series with the same galvanometer to the other side of the switch box so that the currents from these two galvanic sources are flowing through the galvanometer in opposite directions. By means of resistance introduced into the current derived from the ordinary dry batteries, these two currents can be made to equalize each other and the beam of light on the galvanometer scale comes to rest at 113°F. The thermo-couple thermometer is now "set". For each degree of temperature change occurring in the tissues surrounding the thermo-couple, this bar of light travels six mm. on the scale. If there is a fall of temperature in the tissues, the bar of light travels to the left; if there is a rise in temperature, the bar of light travels to the right (Fig. 2).

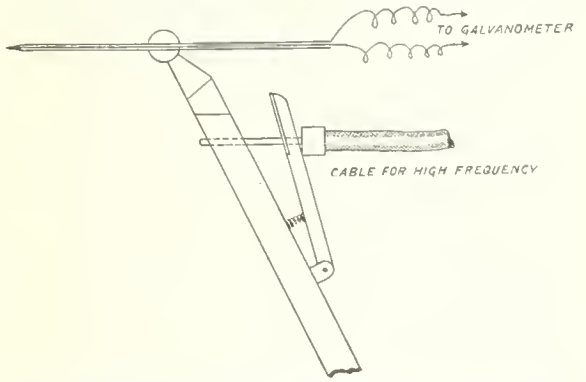

Fig. 1.—Diagram of cross-section of dessication or coagulation point electrode with thermo-couple incorporated; this is used both as an operating electrode and as a temperature recording instrument.

To illustrate the reading of the thermo-couple thermometer after the instrument is "set", suppose we hold the thermo-couple in the air; the beam of light travels rapidly to the left. Now suppose we grasp the thermo-couple between two fingers, instantly the beam of light travels backward to the right, stopping at 93°F. Suppose we insert the thermo-couple into the rectum, the beam of light travels to the right resting at 99°F. Again suppose we dip the thermo-couple into a hot oil bath, the bar of light will swing still further to the right coming to rest at a point on the scale indicating the exact temperature of the water.

The thermo-couple registration is not interfered with by the electric circuit traveling in the Percy cautery iron, nor by the high frequency currents used in coagulation operations so that the thermo-couple can be incorporated in the side of the tonsillectome or snare. One pole of a D'Arsonval current is connected to the tonsillectome or snare and the ends of the blood vessels can be effectually sealed off by keeping the snare at a coagulating temperature.

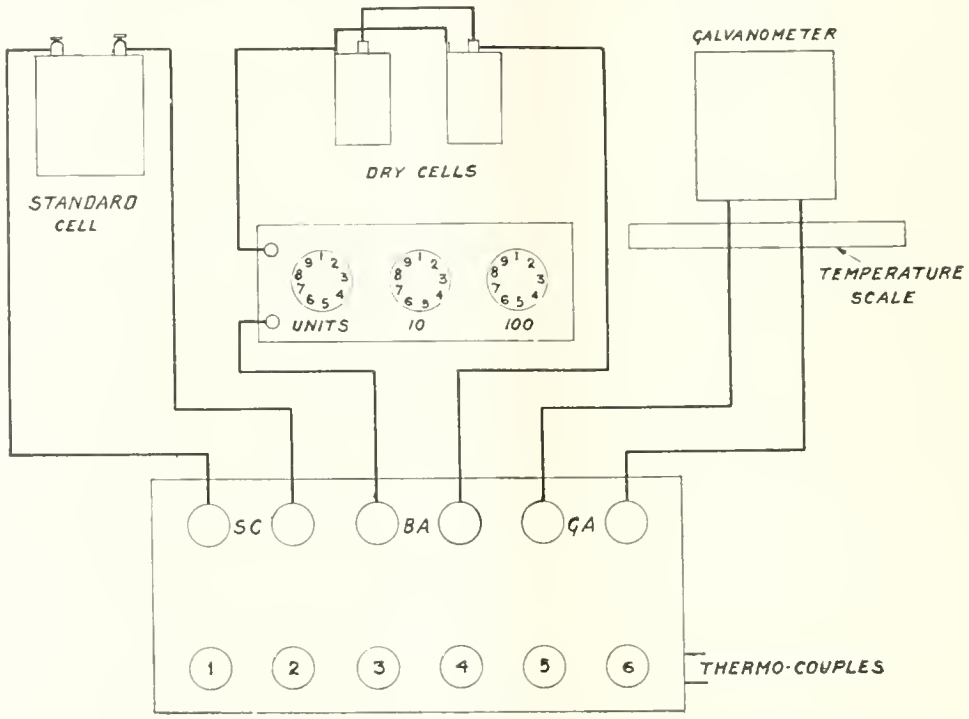

FIG. 2.—Switchbox for selective thermo-couple temperature readings.

Percy iron or in the active electrode used in applying electro-coagulation.

The response to changes of temperature is so quick that a series of thermo-couples can be used on the same galvanometer, and by a selective switch one can read on the same scale, the temperature at any point within the tumor or at a distance providing he can insert a thermo-couple needle into the desired locus. For instance, in the coagulation operation on the uterus (Fig. 3), I would suggest a series of six thermo-couples connected to a selective switch box having six numbered buttons: T. C. (thermo-couple) No. 1 is incorporated in the intrauterine electrode. T. C. No. 2 is inserted into the right broad ligament between the cervix and the uterine artery and ureter. T. C. No. 3 in the left broad ligament between the cervix and the uterine artery and ureter. T. C. No. 4 is inserted into the bladder. T. C. No. 5 is inserted into the rectum. T. C. No. 6 is left free for exploratory purposes in determining the temperature at any desired point during the operation.

By pressing button No. 1, one can read the intrauterine temperature; by pressing button No. 2 or No. 3, the operator can tell how near he is to damaging important extrauterine structures by the heat, etc., so that the thermo-couple acts as a safeguard against heat destruction of important organs.

There is no danger of over-heating the thermo-couple, as it is used commercially in the melting pot of steel mills to regulate the "heat treatment" of fused metals.

In operating on pedunculated growths, especially in cases of hemophilia, leukemia, arteriosclerosis, etc., the thermo-couple should be of invaluable assistance as it can be incorporated in an insulated

A similar procedure can be followed in the bloodless removal of hemorrhoids, and there will doubtless be numerous other uses to which the thermo-couple thermometer can be put in the field of surgery and medicine.

The method of selective heat treatment of malignant tumors will probably be found to be a valuable synergist to radiotherapy.

A study of the accompanying table of coagulation methods will show that Clark and Beer produce their effects with the least amount of current. The difficulty with the other forms of coagulation

has been inability to control and measure the destructive processes. Percy's iron has answered his purposes in the treatment of uterine carcinoma very well and he deserves great credit for having devised, championed, and popularized this method.

Agents which Cause Coagulation of Cells

Methods	Advocates	Nature of Coagulator	Comparative Strength of Currents
Electro-coagulation	Doyen	D'Arsonval high frequency current	1000-3000 milliamperes (Bipolar)
Electro-thermic coagulation	Pfahler	D'Arsonval high frequency current	1000-3000 milliamperes (Bipolar)
Diathermy	Nagelschmidt	D'Arsonval high frequency current	1000-3000 milliamperes (Bipolar)
Desiccation	Clark	Oudin high frequency current	1 milliampere or less (mono-polar)
Heat coagulation	Percy	Cautery iron heated by the ordinary illuminating electric currents	No current directly enters the body; current strength used in cautery 3-10 amperes
Ionic surgery	Massey	Galvanic current	500-1000 milliamperes
Oudin spark (wrongly called fulguration)	Beer	Oudin high frequency current	1 milliampere or less (mono-polar)
Caustics (massive)	Strocbel	Chemical	
Acetone coagulation	Gelhorn	Chemical	

The instrument employed is too large to be used generally throughout the body; its insertion is accompanied by unnecessary traumatism. The D'Arsonval high frequency currents avoid these two objections. The coagulation by Percy's method (heat *radiating out* from cautery iron) and desiccation as employed by Clark have been more under control than the coagulation by the D'Arsonval high frequency currents, which are conducted *through* the tissues and with which the point of maximum temperature has been, not *at* the electrode, but at an indefinite point within the tissues themselves. There has been no accurate method of estimating the heat or effects of either of these processes.

It is to meet these very important conditions and make selective heat treatment in medicine scientific, accurate, and therefore safe, that the principle of measuring heat by the employment of thermo-couples should be employed. The accompanying illustrations show such an apparatus arranged with a scale of measurement suitable for use with any of the operations where coagulation is produced by heat.

THE ADVANTAGE OF KELLY'S METHOD OF CYSTOSCOPY IN WOMEN.*

By HIRAM N. VINEBERG, M.D., F.A.C.S.,

NEW YORK.

In view of the marked recent improvements in electrical prism cystoscopes, direct or indirect, the question arises whether Kelly's method has any further field in cystoscopy. It will be the contention of the writer that it has and that, for the gynecologist in particular, it still possesses many advantages over any other method.

In the first place, so many gynecological patients suffer more or less from dysuria and frequent micturition that the gynecologist for the most part must be prepared to examine these patients' bladders himself. Very few gynecologists have the means or the time to become experts in the use of the prism cystoscope, and unless the gynecologist is expert in the method and has gained a large experience in it, he will frequently be misled by trying to interpret what he sees with the prism cystoscope. With the prism cystoscope, as with the microscope, accuracy in observation and correctness in interpretation call for sole devotion to that line of work, in other words for specialism. This is not so, at least, not nearly to the same degree with the Kelly method, for as soon as one has acquired the art of using the instrument, and this does not take long, the observations are made with the naked eyes, without the medium of any agent but the atmosphere. Thus errors in observation are eliminated, and no special art or experience is required to distinguish the slightest changes in any part of the bladder interior.

The simplicity of the method and the absence of any features which may lead to misinterpretation have often been the means of leading the writer to a correct diagnosis, when other men with larger experience in genitourinary diseases have been in error. In the second place, it occasionally occurs that a condition of the bladder is present that makes it impossible to examine the interior of the bladder with a prism cystoscope, requiring, as it does, a certain amount of clear liquid medium. Take, for instance, a very irritable bladder with extensive tuberculous ulcerations, in which the smallest quantity of fluid is immediately ejected with great tenesmus, even with free cocainization of the bladder. In illustration, one case in the writer's experience will suffice:

A highly neurotic girl of eighteen, with a very irritable bladder due to secondary tuberculous cystitis, was sent to me for diagnosis. It had been assumed that the bladder affection was secondary to renal tuberculosis, but it had not been possible to determine which kidney was affected or whether both organs were, as the patient was entirely free from pain in either kidney region and palpation could not detect any enlargement or tenderness in either side. An unsuccessful attempt had been made on three different occasions, in one of which more than an hour and a half were consumed, by one of the best-known genitourinary surgeons in New York City, to obtain a view of the bladder interior or to catheterize the ureters. By cocainizing the bladder and placing the patient in the knee-chest position I could readily with a small Kelly cystoscope catheterize both ureters. The collected urine from each ureter showed that the right kidney was the one involved, and on its removal it was found to be riddled with tubercular ulcers.

Thirdly, the great majority of bladder disturbances in women are due to a localized cystitis frequently limited to the trigonal area. These cases will usually resist the ordinary method of treatment and will yield only to a direct application of

*Read at a joint session of the American Gynecological Society and the American Association of Genito-Urinary Surgeons at White Sulphur Springs, W. Va., May 19, 1915.

solutions of nitrate of silver of varying strength. These applications can effectually be applied only through a hollow tube such as Kelly's cystoscope with the patient in the knee-chest posture. In any other posture it is well-nigh impossible to have the field entirely free from urine, and we know how futile it is to apply solutions of nitrate of silver to an ulcer or hyperemic area bathed in urine.

Thus, in Kelly's method we have at once a ready means of diagnosis and a most effectual way of curing the patient. Time and time again patients have presented themselves at the writer's office, who for several months had been treated with all kinds of drugs internally and all kinds of bladder irrigations without any appreciable relief. At their first visit a cystocopy with the Kelly tube in the knee-chest posture would be made and catarrhal ulcers or trigonitis would be found. An application with a 10 per cent solution of nitrate of silver would be made then and there. A week later these patients would return, saying they were markedly improved, and a few more similar applications, made weekly, would effect a complete cure.

Fourthly, the removal of foreign bodies and small growths can be more easily accomplished through the Kelly tube and with simpler instruments than through any other form of cystoscope.

To sum up, Kelly's method of cystoscopy is so easily learned, and is so free from errors in interpretation that it forms the method *par excellence*, for the gynecologist who has neither the time nor the vast experience necessary to become an adept in the use of the prism cystoscope. Further, in addition to being an easy method of diagnosis, it forms at the same time a ready means of making topical applications directly to the diseased areas and for the removal of foreign bodies and small growths.

751 Madison Avenue.

THE DEPENDENCE OF TUBERCULOSIS UPON RESPIRATORY INSUFFICIENCY OF THE UPPER AIR TRACT.

By W. SOHIER BRYANT, A.M., M.D., F.A.C.S.,

NEW YORK.

For a great many years physicians all over the world have been interested in discussing the point of entry, as well as the method of infection of the bacillus of tuberculosis. Naturally, nose and throat specialists are more particularly interested in this subject and they agree without a dissenting voice, that the bacilli must enter somewhere in the upper air tract. Having once effected an entrance, they pass on to the neighboring lymph gland and then work their way to their final destination, wherever that may be. These specialists also agree that an abnormal mucous membrane is less resistant to these insidious infections than the normal membrane.

One of the most important requirements for the prevention of tuberculosis as well as for its treatment, is an abundant and continuous supply of fresh, pure air. Another requirement, every bit as necessary as the fresh air supply, is a healthy mucous membrane.

Any rhinopharyngeal obstruction removes the possibility of the presence of either of these requirements for immunity to tuberculosis. It cuts off the supply of fresh air to such a degree that it is impossible for the individual to get a sufficient amount, much less the abundant supply that is essential to combat effectively the bacilli of tuberculosis. The obstructions inhibit free breathing and lung expansion, favoring imperfect expansion and giving the obvious result of under-oxidation. The obstruction also develops an abnormal mucous membrane, making it more susceptible to infection through these bacilli by providing just the conditions most favorable to their growth and development.

The author has noted in the cases of tuberculosis observed, especially at the time of the primary infection, an abnormal mucous membrane as well as obstructions of the rhinopharyngeal passages. Later in the course of the infection, these abnormal conditions may not be so strongly marked, and therefore are not as often associated with the infection in the minds of general practitioners and lung specialists.

Therefore, as the most successful means of prophylaxis, I advocate, not out-of-door life; not an abundance of fresh pure air; not avoidance of overcrowding; not forced feeding; not the absence of tuberculosis bacilli, either human or bovine, from the food; not the segregation of infected individuals; although all these are useful measures, but I do advocate the providing of free rhinopharyngeal passages, which prevent an abnormal susceptibility of the mucous membrane and allow a free ingress of a sufficiently abundant supply of fresh, pure, stimulating air to the lungs.

19 West Fifty-fourth Street.

MULTI-POLLEN VACCINES IN THE TREATMENT OF HAY FEVER.

By HENRI ISKOWITZ, M.D.,

NEW YORK.

History.—A connection between a form of periodically recurrent rhinitis and the flowering seasons of certain plants was noted by a number of writers as early at the seventeenth century. Bostock[1] in 1819 established the clinical entity of hay fever, and analyzed twenty-eight cases which he had collected. Subsequently La Forgue[2] and Le Chambre[3] elaborated on Bostock's observations. In 1873 appeared Blackley's[4] classical monograph, in which he detailed exahustively a series of observations made for the purpose of determining the immediate cause of the disease. He proved that the impact of the pollens of various flowering plants on the mucous membranes of the upper respiratory tract caused the characteristic symptoms of hay fever. Wyman's[5] monograph, in 1876, corroborated Blackley's results.

In 1884 Sir Morell McKenzie[6] recognized the importance of a local diseased condition of the mucous membrane as a predisposing factor. Dunbar[7] began his exhaustive scientific study of the pollens as a causative factor in hay fever in 1895. His monograph, published in 1903, described his first experiments with pollen serum in the treatment of the disease. This was followed, in 1907 and 1911, by papers in which he details the results of his serum treatment during the intervening years.

Dunbar's investigations prompted Wolf-Eisner[8] to a thorough clinical study of hay fever. The results of his observations were published in 1906. Wolf-Eisner rejected Dunbar's antitoxin theories, and suggested that this disease is a condition of anaphylaxis. Weichardt[9] proved the soundness of this theory.

Etiology.—In connection with the pollens as the exciting cause, we find certain other contributing

causes in hay fever. The etiology embraces actually three conditions:

(1) Predisposing constitutional causes.

(2) Pathological conditions of the nose.

(3) The pollens.

1.—We frequently find members of the same family suffering from this condition. In a large percentage of the cases indeed a family history evidencing neurotic tendencies has been found. The opinion is, in fact, very widespread that a disposition to hay fever is always an expression of a neuropathic tendency. It is claimed also that faulty metabolism may play a certain part as a causative factor. What essential pathological condition exists in neurosis is, however, problematical.

2.—We are largely indebted to Roe of New York and Daly of Pittsburgh for the recognition of the local causes. These include: (*a*) Hypertrophic rhinitis; (*b*) spurs and bony projections; (*c*) septal deviations; (*d*) polypi, hypertrophy of the nasopharynx; (*e*) sensitive areas.

3.—There are about thirty flowering plants which grow in this climate, the pollen of any one of which may act as the exciting cause in hay fever. Certain of these are, however, of much greater importance than others, owing to their wide distribution. The periodicity of the disease coincides with the blossoming seasons of the commonest pollen-bearing plants. From the latter part of May to the middle of July the atmosphere is heavily charged with the pollens of the *Gramineæ*. These include the grasses (timothy, redtop, June grass, etc.) and several of the cultivated cereals. As a result of these pollens we have during this period a form of hay fever commonly called rose-fever or rose-cold. From the middle of August the most widely diffused pollens are those of the golden rod, ragweed, and Indian corn.

Geographical Distribution.—Hay fever is prevalent throughout the United States, with the exception of certain districts. These are the White Mountains, the Adirondacks, the Rockies, the Lake Superior country, and certain portions of the Southern States. The immunity of these districts springs from the fact that the flora of the mountain districts differs materially from that of the valleys.

Pathology.—The structural changes of the mucous membrane consist of hyperemia, edema, and enlargement of the turbinal bodies. The hypersensitive areas are chiefly found at the terminal endings of the spheno-palatite ganglion. This is due to the irritation of the sensitive endings of the nerve fibers. Gross pathology has already been discussed.

Symptomatology.—The symptoms of the June fever and of the autumnal type are approximately the same. They are those of acute coryza, malaise, elevation of temperature, sneezing, serous discharge from the nose, obstruction to breathing, lacrymation, suffusion of the conjunctiva; the pharynx is dry; difficulty in breathing may ensue, followed by coughing and asthma. The secretion is acrid and excoriates the skin.

Treatment.—It is all-important that both the constitutional and the local causes be eliminated. In this connection diatheses and faulty metabolism should be treated.

Local hypertrophic tissue should be operated on, septal deviations corrected, and spurs and bony projections removed. Sensitive areas should be cauterized.

Serum Treatment.—The work of Clowes[9] and Koessler[10] has demonstrated the practicability and clinical value of immunizing hay fever sufferers by pollen extracts. This has stimulated extensive study of this form of immunization. The most recent publication on the subject is a paper by Oppenheim and Gottlieb.[11]

Clowes vaccinated eight patients, all of whom experienced a marked benefit. Freeman[12] reports 84 cases treated with pollen vaccines, of whom 64.6 per cent. were completely cured, 23.9 per cent. showed slight improvement, 11.5 per cent. were not benefited. Of twenty-one cases reported by Manning,[13] 66 per cent. were relieved, 33 per cent. were not relieved. Koessler has treated forty-one patients. He reports four as completely cured, 29 improved markedly, five slightly improved, three not affected. Oppenheim and Gottlieb treated eleven cases before and during the hay fever season. Five were cured, four markedly improved, two showed no improvement. In the rose-fever of recent occurrence twenty-four cases were treated with the multi-pollen vaccines; sixteen were markedly improved, eight not affected. The marked improvement consisted of a milder and shorter attack, a disappearance of nervous and constitutional symptoms, and an ability to remain in pollen-infected districts.

Immunization.—The nasal secretions contain a digestive enzyme, which has the marked property of splitting proteids. The resulting proteolysis is akin to that of the stomach and intestinal digestive processes. Thus is explained the bactericidal action of the nasal secretions.

Pollen in the nose is split into albumins, globulins, proteoses, and amino-acids. Under normal conditions there is no absorption of these products. Such absorption does, however, occur in the pathological conditions enumerated in our paragraph on etiology. The result of this absorption is an injury to the epithelial cells of the mucosa and the endothelial cells of the finer capillaries. This is followed by, first, an increased permeability of the cells; second, a specific protective ferment against the protein (sensitization). With this local reaction, an absorption and a sensitization of other parts of the body takes place. A vicious circle is thus established, in which a parenteral digestion of the proteins of the pollen in the nose acts as an excitant.

The proteins thus absorbed consist of the pseudo-globulins, euglobulins, and albumins. Only the albumins contain the toxin. The toxin is specific.

As a result of the parenteral absorption of foreign proteins a specific immune or antibody is formed. This may become attached to certain cells, or remain free. When there is a surplus of free antibody we have immunity. With little antibody, and that attached, we have the sensitized state. The reaction takes place when the protein and the fixed antibodies are united. The symptomatology is determined by this reaction.

Experiments have shown that minute doses of pollen proteins applied to the conjunctiva or to the scarified skin produce in patients who are sensitized characteristic symptoms. The strength of the dose which can thus be administered without causing any symptoms determines the level of resistance. We first establish in every patient the toxic dose, by the instillation of one drop of pollen extract in the conjunctival sac. The resulting ophthalmic reaction serves two purposes: (1) diagnostic; (2) determination of resistance.

Koessler has worked out a pollen unit. This is equal to one one-hundredth part of a millionth of a gram of pollen protein, and designated as P. U. The unit has been adopted in all subsequent experiments with pollen extracts. The resistance to the ophthalmic reaction is expressed in these units, and the immunizing doses are thus determined.

Preparation of Vaccine.—All patients subject to rose-fever react mainly to the pollens of the *Gramineæ*, and those of the autumnal type to ragweed, golden rod, etc. All are, however, multisensitive—that is, they react to several different pollens. Many, indeed, are sensitive to both groups, the spring and the autumnal.

In the preparation of the serum some twenty types of pollen are used. These include all species of both *Gramineæ* and *Compositæ* which have any marked influence on account of wide distribution.

The pollens are gathered and dried under sulphuric acid. They are then ground in an agate mortar as finely as possible and sifted through a fine silk filter. The pollen is then dissolved in an 8.5 per cent. salt solution, in the proportion of a centigramme to 10 cubic centimeters of the fluid. The solution is then placed in an incubator at 30° C. for twelve hours, and then filtered through a sand filter. To this solution is added ten times sterile distilled water plus .25 per cent. phenol and .5 per cent. glycerine. This is the standard solution, from which all injections are prepared, Koessler's pollen unit being used to determine the strength ratio.

Dosage and Administration.—The treatment consists of fifteen doses of multi-pollen vaccine, administered subcutaneously in the interscapular region, using the same precautions as with any hypodermic injection. The interval between injections is three to five days, depending upon the reaction. The duration of treatment is from four to six weeks. It is desirable to make this treatment a prophylactic one, in order to obtain immunization before the onset of an attack. Encouraging results are obtained, however, when the disease has already developed. Of the twenty-four cases treated with the multi-pollen vaccines, fifteen were treated during the attack.

Treatment should be begun some eight weeks prior to the hay fever season. Severe reactions may result after the first injection. These promptly disappear after twenty-four hours, and do not recur after subsequent injections.

Immunity.—This varies with the individual. Some patients carry their immunity over the ensuing year, others do not enjoy this extended immunization. In these cases, while active immunization may not be realized, the attacks in the following season are less severe, milder in their inception, and last a shorter time. It is important that patients be treated for several years with the vaccines in order to obtain a permanent cure.

THE RELATION OF LOW TEMPERATURE FERMENTATIONS AS AFFECTING SANITARY CHARACTER IN MILK.

BY J. M. W. KITCHEN, M.D.,

EAST ORANGE, N. J.

Previously Practised Methods Inadequate.

THE prevention of primary infections of milk at the places of its production has unquestionably been of great importance in securing safe and edibly excellent milk in a small part of the public supply, but it is becoming evident that such preventive work is not entirely adequate in securing the very highest quality of milk. Important auxiliary action seems to indicate that regular exercise of cattle is needed to prevent the transfusion to milk of those cellular excretory accumulations in the bovine tissues which pertain to sedentary habits, and which follow deficient heart action and non-muscular expression of such waste matters from the tissues, and insufficient active elimination through the ordinary channels.

There are more or less volatile and diffusive matters transferred to milk from the tissues of the cow that have originally been formed through bacterial action in the cow's hide and that have been absorbed into the blood through the respiratory and circulatory organs, as well as certain principles absorbed from tainted, objectionable food. These matters should be more completely eliminated from milk by improved methods of aeration. There is no evidence that they are seriously harmful, although they may be nauseating, and certainly cannot be of any benefit, and being of an excretory nature, it is possible that they are somewhat damaging.

A more general recognition should obtain of the need of *proper* pasteurization of *all* milk, and its pasteurization in the final container, in order to eliminate all possibility of man's pathogenic infections, whether bovine-tuberculosis, typhoid, or other infections conveyed by infected water, insects, or human conveyors who handle the milk. An adequate protection of the entire lip of the bottle and preventing conveyance of infections through the closure seal, as well as ability to pile cracked ice on the tops of the bottles during conveyance to, and until consumption of the milk by the consumer, is highly important.

The most important auxiliary advanced treatment of milk, however, is in connection with its temperature control during the entire time between its production and its consumption. This is a matter that up to the present time has been given very little attention by investigators, and practically no attention in general trade practices. Even very considerable bacterial infections of milk, if from healthy cows, is not so important a matter as is the character of the fermentations which occur in the milk during its handling. Refrigeration has been mostly practised to prevent souring of milk. Proper pasteurization provides against danger from patho-

genic germs, but nothing practical except adequate and sufficiently deep refrigeration will prevent the accumulation in milk of excretory and decomposition substances due to bacterial activity at the ordinary temperatures at which milk is usually handled, which temperatures may prevent souring of the milk, but do not sufficiently prevent proliferative activity of such germs as may have gained access to the milk.

In discussing the subject of The Relation of Low Temperature Fermentations to Sanitary Character in Milk, in referring to "low" temperatures, I mean temperatures varying between 30° F. and 70° F. The conclusions I have arrived at have been based more on the investigations of others, than my own, including such investigators as Park, Holt, Mendel of the Shepard (Yale) Laboratory, and others, but the conclusions I have reached, and from perhaps a wider study than has been given by others, is somewhat different from those which are generally held. I think that a decided step in advance in securing safety in the milk supply will be through the practice of a very much deeper refrigeration of milk during the entire time of its handling than has been customary. It has been customary at certain times of milk handling, especially if for long shipment, to deeply refrigerate it, but not enough consideration has been given to the deteriorations that may occur during comparatively short periods of holding. The presence of even small quantities of the products of bacterial activity cannot be of any advantage or be other than unwholesome, and there seems to be no reason to doubt that their damaging effect may be proportionate to the extent of their presence. In other words, the presence in milk of fermentative products largely determines the mere wholesome or unwholesome, as well as dangerous quality of milk.

It is now generally agreed that pathogenic infections of milk are dangerous, and that all effort should be taken to prevent or remove such infections, but there is apparently great lack of recognition of the fact that the amount of excretory bacterial products or of decomposition protein products due to bacterial action, may be and probably is, individually damaging to all grades of human beings in proportion to the resisting powers of individuals. It is a known fact that large bacterial contents of milk do not very disadvantageously affect infants in cold weather, while the same infection would act seriously when the constitutional resistance is reduced by high atmospheric temperature and moisture. This does not say, however, that large bacterial contents may not be injurious even in non-fermented milk. Such large numbers may, and probably are irritating to the alimentary surfaces, but the presence of the products of bacterial action are productive of different effects, and usually of a constitutionally depressing character.

In view of the fact of the very large numbers of varieties of bacteria found in milk originating from the cow, or from sources outside of the cow, it does not seem practical to do other than to divide milk bacteria into two designated classes, namely, (1) those of the "lactic acid" type, and (2) those of the so-called "putrefactive" type, some of the latter of which at least may be malign in influence.

The malign influences are potent in proportion to the rate of activity of the malign bacterial increase, and it should be accepted as true that because that influence may be only small, there is no valid excuse for submitting dietetically to such influence. The fact that one individual, or a large number of individuals, may have resisting powers in excess of others, is no proof that such resistants are not injured in health in proportion to the influence acting on them. There is no good excuse why the public milk supply should not be relieved entirely from all suspicion as to unwholesomeness, as well as of dangerous qualities, it being merely a question of adding an increase of 1 cent a quart to the price to the consumer to secure relief.

In support of the proposition that the writer is presenting, let us consider the evidence that is available for the forming of his conclusions. Let us start by allowing that toxic milk is usually not the only or principle cause of diseased conditions in infants. Lack of intelligent care, and also the depressing effects of atmospheric heat and moisture, as well as inherited individual powers of resistance, tendency to growth, etc., must be given full prominence. We know that bacteria may render milk dangerous. We know that the more free milk is from infections when produced, the more safe and wholesome it is. We know that depreciation in it is due to the influences of heat, time of holding, and of sanitary handling. We know that bacteria proliferate more or less rapidly between the temperatures of 20° F., for some varieties, and possibly even up to 150° F. for some other varieties, every variety, of course, having its optimum favorable temperature for increase. The lactic acid optimum is between 60° F. and 80° F., while that of some of the putrefactive forms may be near 100° F. At temperatures approximating 32° F., and while milk preserves its antifermentative qualities at least, bacteria do not appear to reproduce themselves in that fluid. For several days *fresh* milk may be considered safe at that temperature, but stale milk at that temperature, if given time, grows billions of germs.

In fresh milk bacteria propagate at various temperatures to an extent somewhat as follows:

	In 24 hours.	In 48 hours.	In 96 hours.
At 39° F.	25 per cent.	2 fold	6 fold
At 42° F.	35 per cent.	6 fold	200 fold
At 46° F.	70 per cent.	10 fold	400 fold
At 50° F.	2 fold	600 fold	
At 55° F.	6 fold	1200 fold	
At 60° F.	30 fold	5000 fold	

From the above it will be inferred that a very considerable amount of excretory and decomposition matters may be produced even from small primary infections, at moderate icing temperatures, and if the primary infection is malign such production may be dangerous. What must be the result of large infections? It is evident that if the character of the infections primarily are malign, the damaging possibilities must be at least somewhat serious, and may be extremely serious. Now, the holding of market milk at temperatures above 50° F. is very much more frequent than milk held below 50° F., especially after the milk is delivered to the consumer.

From the above it will be seen that when milk is held at or below 45° F., and if fresh, and not held for more than twenty-four hours, it will not accumulate great amounts of bacterial products, but it will also be seen that if there is a large primary infection, there will be a large presence of bacterial products at temperatures even below 45° F., from a twenty-four hour holding, and with milk, a holding

of three days before its consumption, even with "modified certified," is far from uncommon.

There is no evidence that the mere presence of large numbers of bacteria in milk is dangerously harmful, as has been previously stated, but all the evidence in hand goes to show the possibility of damage due to the presence of bacterial products resulting from fermentation in the milk itself.

We know that decompositions of organic proteins may result in the formation of toxic matters, and we may assume that excretory products from bacterial activities may be harmful, inasmuch as a general proposition may be accepted to the effect that all excretory matters are more or less harmful, unless further organic and chemical reducing changes occur in them. It is presumed that in all activities of living forms there are excretory matters produced, and decompositions result from bacterial activity in the food on which the living forms subsist. As applied to cow's milk infected with micro-organisms, these products may be formed before the milk is consumed, or after it is taken into the alimentary tract. With our present knowledge, we cannot state definitely the amounts of either product that may be formed, but probably both are formed.

While it is highly important that infections of milk should be prevented as much as possible, it is a question whether it is not fully as important, if not more so, that proliferation of the infections that have occurred at the places of production of milk be prevented. If they are prevented either by treatment of the milk before consumption, or by not ingesting more of the milk at any one time than can be quickly digested, it does not seem to be a matter of supreme importance as to slight variations in the amount of primary infections, inasmuch as the damaging excretory and decomposition products are not then formed in large amounts, while most of the infecting germs pass out of the intestine with the intestinal dejections.

Those workers who have been depending solely on preventing infections should now take the further step of advocating as a precautionary measure of safety, the *entire* prevention of all fermentations in the milk. This is so simple a matter to effect through mechanical refrigeration that there seems to be no excuse whatsoever for neglecting to eliminate the possibilities of not carrying out such preventive treatment.

Quality of Milk and Its Selling Value.—The greatest obstacle to the milk reform is that most consumers think that as they have got along pretty well under old conditions, it does not seem worth while to better those conditions. It is obviously true that the greater part of consumers of market milk do not show immediate damage from the effects of deteriorated milk. The same thing may be said in connection with nicotine and alcohol, yet both of these products act as deadly poisons in large enough quantities, and when habitually consumed in moderate or small amounts, exert a more or less immediate effect in reducing general vital activity, and indirectly, in shortening life. The same reasoning may be applied to milk that has become deteriorated in quality through the accumulation in it of bacterial products. Because milk is so good a culture medium for germs, this consideration applies even more to milk than to other foods. But no form of decomposed food can be said to be positively wholesome.

There is always more or less of such products in all market milk. If in sufficiently large amounts they kill strong adults quickly. In small amounts strong individuals do not immediately show damage, but there is no question that some damage is done that would not have occurred if absolutely unchanged milk of high sanitary character had been used.

Is there any excuse for neglecting to use milk of the very highest attainable character, when it is such an important food? If defective as a food, and if fed in frequent and moderate doses to infants or other susceptible persons, it kills more or less quickly. There are multitudes of the very delicate to whom the difference between consuming perfect milk and dangerous milk is the difference between life and death. It will pay even the strong and healthy to consume only the best milk, as well as other foods. If there is need of economizing, economization should be effected in quantity, and not in accepting defective quality.

Milk and butter that are markedly dangerous to life because of the presence of disease-producing germs, should, through the action of municipal interference, not be allowed to be used.

Again, it should be emphasized that mere dependence on clean milk is not a sufficient guarantee of safety.

Apparently the same obstacle will be met in carrying out the milk reform that is being met in fighting alcohol. Ignorance assumes that because it does not detect a damage due to the poor quality of milk, such milk is safe. No one in his senses, unless grossly ignorant, who believed that a milk contained typhoid and other pathogenic germs, would consider the consumption of that milk a safe performance without heating the milk sufficiently to destroy those germs. Risks should not be taken in this matter. There are untold multitudes of consumers who consider properly pasteurized milk unhealthful, and there must be a very considerable proportion of the medical profession that does not realize that so-called putrefactive fermentations in milk result in the production of bacterial excretory and decomposition products in the milk, and that such products in the milk are damaging according to the amounts present, and the frequency of consumption of such matters.

We as yet have no definite knowledge of how to determine the presence of such matters quantitatively and qualitatively, but we do know that small or large infections of milk increase into innumerable billions of bacteria at various temperatures not very far above the freezing point. We know that there has been something in the milk in the past that has killed innumerable babies. We know that pasteurized milk especially will ferment at a wide range of temperatures. We know that butter will depreciate quickly at a temperature of 40° F., and that it requires a temperature below 20° F. to prevent its deterioration in long cold storage. The trained sense of taste can detect change of flavor in stale milk that is not due to souring of the milk.

We know that there are undetected conveyors of tuberculosis in many herds of cows. We know that one fly may carry typhoid germs and effect a wide-spread typhoid epidemic, and yet many medical men advocate the use of raw milk in the case of delicate infants and invalids, and do so in face of the fact that there is no condition known that could be produced by a properly pasteurized milk that cannot be corrected by feeding

a little fruit juice, or other modifying nutriment. Perhaps these same individuals may not believe in the accumulation in milk of possible fermentation toxins from low temperature fermentations.

One very important precautionary measure is too generally neglected, and that is the adequate refrigeration of infant's milk *after* its passing from the purveyors' hands, and this particularly applies to modified pasteurized milk. This should be attended to by the purveyor. It is a very common occurrence in milk of this character to have had some of it held for three days before it is entimely consumed by the infant, and for a part of that time held at temperatures in which fermentations occur with considerable rapidity, and especially after the milk has been modified and pasteurized. To secure the best results milk modified at the laboratory should be placed in the feeding bottles *at the laboratory,* completely sealed, and then kept completely covered with cracked ice until heated for immediate consumption. Milk of this character should be delivered in special refrigerative containers, labeled with full directions to the consumer as to adding further ice to that originally provided, so that there can be absolutely *no* fermentation occurring in the prepared milk up to the immediate time of its consumption.

So far as physicians and purveyors are concerned, they should take no risks in these matters by neglecting to eliminate the possible occurrence of depressing influences in the alimentation of individuals of all ages and degrees of resisting power. This applies particularly to milk as well as to other foods.

The Perfect Milk.—Normal milk is justly considered a perfect food, as well as the most economical of animal foods, but emphasis should be made that its life-giving, as well as its best pleasure-giving qualities, usually depend on preventing changes from occurring in it that are represented by contaminants at any time, whether from absorbed disagreeable or dangerous taints, or from physical changes due to infecting bacterial activities. In nature there is little opportunity for the occurrence of changes in milk in the time between its production and its digestion after consumption, but it should be remembered that the peculiar sociological conditions of modern life necessarily involve the receipt by milk of the influences of heat and long time holding of the milk, besides more or less of primary germ infection.

To secure a perfect milk for the consumer, or one that is relatively perfect, necessitate co-operative efforts on the part of producers, dealers, *and* consumers, in preventing changes from occurring in the milk. Teachings to that effect should be pronounced and wide-spread.

There is considerable nonsense printed in the general press regarding the milk situation. Nevertheless, it is desirable for the public to know the full facts relating to this important matter; and in particular, the medical profession and health authorities should understand it fully so that an intelligent planning can be formulated and applied in remedying the objectionable conditions of the situation.

As a matter of fact, much information is still lacking in regard to the situation on the part of those who ought to understand it thoroughly. The more progressive dealers are doing about as well in their practice as could be expected, considering the information they have in hand; but so far as my personal observations go, no commercial dealers are doing as well as is desirable. Certainly, the public should be given the privilege of purchasing absolutely safe and edibly high class milk at reasonable prices. The public has not that privilege at the present time.

So far as that part of the public supply is concerned that is pasteurized in bulk under the best methods, the worst that can be said of it is, that it is not as wholesome as it might be, that occasionally it may be pathogenically infected during its bottling and handling, and that it may become, and usually is, infected through the bottle closures in use. Such infections, however, are usually harmless, they do not become greatly increased by holding at too high a temperature for short periods, or for longer time at low temperatures. The greatest danger usually comes through the small dealers, who are ignorant and who may be unscrupulous. There seems to be no reason to question that it is the moral duty of all health boards to act as quickly as possible in preventing such dealers from pursuing a business that calls for such care and special knowledge.

94 Prospect Street.

THE CAUSATION AND TREATMENT OF PELLAGRA.

By THAD SHAW, M.D.,

San Antonio, Texas.

After a continued study of both the clinical and pathological aspects of pellagra, I have come to the definite conclusion that pellagra is a metabolic disease. Others have called it a chronic intoxication, but I think this term is too vague and too abstract. Poverty and bad hygiene aggravate or furnish a favorable soil for this disease the same as for all diseases, but do not of themselves cause the disease, except in this respect, that the economic condition of a country determines the diet of the people. Pellagra appeared in France soon after the reign of Napoleon I, which was a period of extreme poverty in that country. France recovered from this economic depression in the latter part of the nineteenth century and pellagra decreased to such an extent that the disease is now a very rare one. Taking this one fact together with the history of the disease, the countries in which it is most prevalent, Italy and Egypt, together with the fact that it has not been described in any aborigines or primitive races, and reasoning from the known cause of beriberi and its variety of symptoms and forms, and taking into consideration furthermore the lack of definite or characteristic post-mortem lesions in pellagra, I have arrived at the conclusion that the fault lay in the metabolism of the foodstuffs. Bearing upon this same point, I have considered the strange effect of etherization upon a pellagrin; ether anesthesia more than chloroform anesthesia always aggravates and in a great many instances relights the disease, acting very much in the same way as an anesthetic does when it causes delirium tremens in an alcoholic. Whether the etherization adds toxic metabolic substances or destroys necessary products of metabolism, I have been unable to determine. As a rule all pellagrins are vegetarians in entirety or greater part. And there exist in the carbohydrate foodstuffs toxic substances or a lack of vital substances which, when the foodstuffs (themselves not necessarily spoiled) are con-

sumed over a more or less long period of time, produce injurious effects upon the organs of the body.

All physicians who have had experience in treatment of pellagra agree upon one point, and that is that the milder cases improve if kept in a hospital in bed, at rest, and upon a fairly liberal diet with plenty of fresh meat or meat juices. Ordinarily pellagrins consume a large carbohydrate diet. And in this connection it is interesting to know that only in the last few years has the difference in composition of proteins been brought out. Fischer, Abderhalden, Mendel, and Osborne have shown the great variation in composition of proteins in regard to content of various amino-acids. Certain proteins lack or are deficient in certain amino-acids necessary for growth and maintenance. All proteins derived from animal sources, with the exception of gelatins, seem to be suitable for human consumption as they contain all the necessary components in right proportion. Some of the vegetable proteins are deficient in this respect but as yet it has not been sufficiently proven which article of diet is the offending or causative agent. Funk claims that vitamines are essential for the maintenance of the health. Animal foods and vegetables contain these in varying amounts; meats are especially rich; polished rice is devoid of them. Funk argues that pellagra is a disease due to the lack of vitamine in the food, analogous to the production of beriberi through the large consumption of polished rice.

The Thompson-McFaddin Pellagra Commission has worked in Spartanburg county, S. C., where practically all pellagrins are mill hands and conditions are not comparable to other countries where the disease is just as prevalent. Yet they came to these conclusions as a causation: (1) The simulium is discredited. (2) Animal inoculation and experimental study of intestinal bacteria have not yielded conclusive results. (3) No evidence of inheritance is obtainable. (4) The immediate results of hygienic and dietetic treatment in adults have been good, but after returning to former conditions of environment and living, most of these cases have recurred. The prognosis in children is very much more favorable. (5) Occupation has no influence.

As to the infective nature of the disease the Thompson-McFaddin Commission arrived at only two conclusions which have any bearing upon this point. These are:

1. The American form is more severe, notably more so than that in the West Indies and Egypt; coinciding with the experience that a new disease or an acute infection is more prolific in a virginal soil.

2. The Commission is inclined to believe that pellagra is in some way transmitted to a non-pellagrous person from a pre-existing case and that one of the important factors in this transmission is residence in the immediate neighborhood of a pellagrin. To bear this out the Commission states further that in certain hospitals for the insane we have ascertained that pellagra is usually more prevalent and persistent in the wards housing untidy patients. Only in one case have I seen any evidence of transmissibility and that case occurred in the Austin Lunatic Asylum in a patient who had been in the institution 14 years, yet developed the disease in 6 months after living in the hospital in close contact with a rapidly fatal case of pellagra. The pellagrous patients are more frequent in the untidy wards, yet these wards house the senile dements, the aged chronics, and the more or less helpless idiots in whom gastrointestinal and other nutritional disturbances are more common than in the other class of patients in the same institution in these same wards. The bulk of diet is carbohydrate, consisting of bread, beans, peas, rice, grits, and potatoes, and the disease runs hand in hand in comparative frequency with the occurrence of beriberi. Twelve years ago the Austin Insane Asylum experienced so much beriberi that rice had to be eliminated from the diet, and during the past winter another epidemic of beriberi, though not so extensive, has brought about practically the same results. And when taken into consideration, the facts point more strongly to the carbohydrate element of the diet as the offending factor more than toward a hygienic or infective basis for the disease.

In the treatment of pellagra the most uniform results are obtained by the climatic, hygienic, and dietetic régime. Here in Texas it is best to send all pellagrins when possible to the snows of Colorado, away from the heat and sunlight, and to keep them there until the first of October, and to return them again the following year. This together with a liberal mixed diet in which the carbohydrate element is reduced to a minimum gives the best results in the average case. Whether the diet be liquid or solid, or a milk diet depends entirely upon the gastrointestinal symptoms of the patient. Advanced cases are unimproved by any available treatment and end fatally in shorter or longer period of time. The milder cases are improved by rest in bed, hospital regime and liberal diet in which fresh meat is a large constituent. Vomiting, diarrhea, the skin lesions, and other manifestations must be treated symptomatically.

First and foremost in the drug treatment of pellagra comes arsenic and its salts—Lombroso claimed arsenic in the form of Fowler's solution as a specific. For that reason sodium cacodylate, atoxyl, and salvarsan have been used. Arsenic is beneficial in many cases as a metabollic tonic. I hve used practically all of these arsenic salts without any uniform results. Furthermore I tried auto-salvarsanized serotherapy in six cases which grew progressively worse under my treatment.

The next most widely vaunted and heralded specific agent I might mention is the direct transfusion of blood. In many cases I have seen the skin lesions clear up and the gastrointestinal symptoms temporarily abate, but the mental symptoms were in no way affected. Bennett of Austin reports many recoveries under this treatment, yet I have seen at least two or three of his cases in the Austin Lunatic Asylum with marked mental and intestinal symptoms in the early fall and these showed a recurrence of all lesions in the spring. Direct transfusion of blood serves as a temporary means to add strength and recuperative power, but is not in itself a curative remedy.

Following Cole of Mobile I tried urotropin in eight cases in the Austin Lunatic Asylum. I gave as much as 150 grains per day in plenty of water with no ill effect to the patient, but with no effect upon the disease other than were obtained by hospital régime. Tucker of Richmond, Va., says: "Hexamethylenamine treatment was tried by me because of its property of forming formaldehyde in the body secretions and because of the probability of pellagra being an infectious disease. Hexa-

methylenamine was given to five patients in doses of 5-7½ grains, four times a day over a period of three weeks, all other treatment being discontinued. Two cases were so severe that it looked as if death would be the only outcome, while three other cases were of moderate severity. Such prompt and striking improvement followed the administration of hexamethylenamine that I feel it deserves a more extensive trial." So far as my own experience has gone, I have not had such favorable results in the use of drotropin.

Dr. Dyer of New Orleans claims that hydrobromate of quinine is a specific for the disease. In 1911 at a meeting of the American Medical Association, Dr. Dyer said: "In the treatment of all of my cases I have used quinine hydrobromate and even in advanced cases, with stomatitis and diarrhea, I have often given 10 grains, three times a day, and have kept it up until those symptoms have been controlled. The dose can then be reduced. In addition I have used arsenic which I believe is of distinct service. None of my patients has died and some are now entirely free from symptoms of the disease.

I believe that quinine is of great service in the treatment and cure of pellagra." At a meeting of the Texas State Medical Association, in Houston in 1914, Dr. Dyer further said that he had continued the treatment of pellagra with quinine hydrobromate since his previous report, and that out of 100 cases treated by himself alone he had had no fatal results. My own experience with this remedy has been limited, yet I could see no greater benefit from this medification than from any of the others I have thus far tried.

Dr. Wilson of Corsicana, Texas, used a 1 per cent. solution of picric acid as a local dressing to the skin when inflamed, and internally in increasing doses beginning with 2 or 3 drop doses and gradually increasing as with Fowler's solution. While connected with the University of Texas I had occasion to see this tried in the wards of the John Sealy Hospital. I could see no merit in this plan of treatment whatsoever.

Now I repeat that avoidance of sunlight together with residence in the colder climates, especially the snows of Colorado (for these are very accessible to Texans), hospital régime, tonics, and liberal diet in which fresh meats are plentiful will do more for the pellagrins than attempted specific medication can do. Fresh meat is easily digested, and contains the needed substances. As pellagra is primarily and essentially a metabolic or nutritional disease, it should be treated with this idea in view, and the errors or evils of the diet should be corrected when possible.

As yet the exact causative articles of food or constituent of foodstuffs has not been determined. As civilization has advanced and the stress and strain of living has brought about the hoarding of foodstuffs and the adulteration for commercial purposes, this disease has developed. Whether the causative agent is a toxic product developed in the carbohydrate element or whether it resides in a natural lack of the necessary life-giving and life-supporting elements normally contained within the carbohydrates employed remains to be proven at a future date. The various manifestations or lesions of the disease must be treated symptomatically while the disease itself must be treated from the metabolic viewpoint.

Medicolegal Notes.

Fraudulent Use of Mails.—On a trial for using the mails in aid of a scheme to defraud by representing himself to be a physician and specialist in nervous diseases, inviting the submission of statements of symptoms and, irrespective of what the symptoms indicated, inducing the belief in the patients that they were the victims of serious ailments and in dire need of medical attention, there was evidence of the defendant's competency and experience as a medical practitioner. It was held, however, that evidence that the symptoms which the defendant represented to his prospective patients as alarming evidence of disease were in fact no symptoms of disease at all, but of normal health, was sufficient to sustain a conviction.—United States v. Smith, 222 Fed. 165.

Unskillful Operation — Evidence of Other Offenses Inadmissible.—In a prosecution for killing a patient by an alleged unskillful abortion, resulting in blood poisoning, there was evidence that the patient, who desired to be rid of the child, had herself made use of a syringe, and it was just as probable that she might have introduced the poison as that it was introduced by means of an instrument improperly sterilized in the hands of the defendant. It was held that evidence of prior or subsequent abortions was not admissible. The issue was not whether the defendant was an abortionist, but whether he had produced the death of the patient. The prosecuting attorney having repeatedly obscured the issue by the introduction of evidence of such prior and subsequent offenses, the error was held to be prejudicial, the defendant's evidence, if believed, exonerating him from the charge.—People v. Follette, 164 N. Y. App. Div. 272, 149 N. Y. Supp. 888.

Practising without License or Registration — Chiropractics. — On appeal from a conviction of practising medicine within the State of New York without a license or registration, the defendant claimed to be a chiropractor, or doctor of chiropractics, having graduated from an institution at Davenport, Iowa, known as Davenport University of Chiropractics, in June, 1912. In July following, without having any further examination or receiving any license in the State of New York, he began practice in Brooklyn. He had a sign, with regular office hours, and as a witness he admitted having treated about 200 persons for ailments of the stomach, chest, or spine, also for nervousness, hysteria, and diseases arising from pressure on the nerves. The prosecution proved by a witness whom the defendant had treated that he first examined her ankle, pronounced the arch as having fallen, massaged the foot, and advised a different shoe. On a further visit he manipulated the patient's spine, which, speaking as a spinologist, he pronounced out of alignment in several places. He said he could restore it, but it probably would not stay the first time. He further gave the opinion that the nerves leading to the ankle might be impinged so as to cut off the circulation.

In view of the large increase of those who attempt treatment without drugs or instruments, Legislatures have found it necessary to deal with all who assume to treat or prescribe for physical ailments. Such regulations are within the State's police power. By the New York statute, Public Health Law, Section 160, subdivision 7, one practising medicine is comprehensively defined as a person "who holds himself out as being able to diagnose, treat, operate or prescribe for any human disease, pain, injury, deformity, or physical condition, and who shall either offer, or undertake by any means or method, to diagnose, treat, operate or prescribe for any human disease, pain, injury, deformity or physical condition."

The defendant's sign, his circular and professional card, and his own admissions as a witness, all showed that he held himself out as being able to diagnose, treat, and prescribe for pain, disease, and injury. Rubbing and pressing on the human joints are old therapeutic agents. When accompanied by such attempts at diagnosis as a statement that the patient's pains in the ankle were from the spine having come out of alignment through displaced vertebrae, the defendant's acts came within the statutory definition of the practice of medicine. He was therefore held to be guilty of the misdemeanor of practicing medicine without a license, or being registered under the Public Health Law, Section 174.—People v. Ellis, 162 N. Y. App. Div. 288, 147 N. Y. Supp. 681.

SEPTIC ENDOCARDITIS.

MODERN clinical and bacteriological studies have provided a sharp delineation of the various types of this condition, which less than a generation ago were grouped under the rather inappropriate term "malignant endocarditis." This was regarded as a local disease of the endocardium from which secondary systemic infection arose. To-day ulcerative endocarditis is looked upon rather as a local manifestation of a general systemic infection and is more aptly described by the term "septic endocarditis." G. Jochmann of Berlin, who has contributed much to the knowledge of this subject, presents a comprehensive review of it in the *Beiträge zur Klinik der Infektionskrankheiten und zur Immunitätsforschung*, Vol. IV., No. 1. The septic is to be distinguished from the rheumatic or verrucose type of endocarditis. The bacteriology of the former is distinct. The causative microorganisms are most frequently streptococci; next in order come staphylococci, pneumococci, gonococci, the colon bacillus, and the meningococcus.
